given temperature and solvent for many ions. By convention, it is negative for negatively charged species (anions) and positive for positively charged species (cations). To a certain range it depends on the concentration of the electrolytes (or the ionic strength) in solution. Therefore, the usual data for tabulated electrophoretic mobilities of ions are the limiting or absolute ionic mobilities,  $u_i^0$ . They are the mobilities that are extrapolated for zero ionic strength assuming further that the substance would be completely in the given ionic form. Such conditions can be theoretically reached in infinitely diluted solutions. Table 1 gives limiting ionic mobilities  $u_i^0$  for several ions. The ‘real’ ionic mobilities under a given finite ionic strength and given conditions are called actual mobilities.

The electromigration of charged species in the separation column increases the electric current. The current density  $j$  (in  $\text{A m}^{-2}$ ) at a particular position of the column is given by

$$j = FE \sum_{i=1}^n c_i u_i z_i \quad [2]$$

where  $F = 96487 \text{ C mol}^{-1}$  is the Faraday constant,  $c_i$  is the concentration of the  $i$ th charged species (in  $\text{mol m}^{-3}$ ), and  $n$  is the total number of charged species present. Notice that the product  $u_i z_i$  is always positive, so the movement of positive species in one direction and negative species in the opposite direction contribute to the electric current density in the same way. According to Ohm’s law, the current density  $j$  is proportional to the intensity of the electric field  $E$ ,

$$j = \kappa E \quad [3]$$

The proportionality constant is the specific conductivity,  $\kappa$ , which is defined by the above relation.

The SI unit for specific conductivity is  $\text{S m}^{-1}$ . Obviously, the specific conductivity can be calculated if concentrations, charge numbers, and mobilities of all the charged species are known,

$$\kappa = F \sum_{i=1}^n c_i u_i z_i \quad [4]$$

## Mobility of Weak Electrolytes – Dependence on pH

Most substances behaving as electrolytes, especially organic acids, bases, and ampholytes, are weak electrolytes. Under given conditions their dissociation or protonation is not complete and reaches a chemical equilibrium. Then, significant parts of the substance can exist as ionic forms with various charge numbers or in the neutral form; and all these forms have different velocities. In most cases the acid–base reactions in solutions are very fast so the electromigration of the substance in the electric field can be regarded as the movement of one entity with all its ionic or neutral species moving with a certain mean velocity. Such a mean electrophoretic velocity  $v_A$  of electromigration of the weak electrolyte A is then

$$v_A = \frac{E}{\bar{c}_A} \sum_{k=1}^m c_{A,k} u_{A,k} \quad [5]$$

where  $\bar{c}_A = c_{A,0} + \sum_{k=1}^m c_{A,k}$  is the total (analytical) concentration,  $c_{A,k}$  and  $u_{A,k}$  are the concentration and actual mobility of the  $k$ th ionic species, respectively,  $c_{A,0}$  is the concentration of the neutral form, and  $m$  is the total number of all ionic species of the weak electrolyte A. The above equation allows a definition of the effective mobility  $\bar{u}_A$  of the weak electrolyte A:

$$\bar{u}_A = \frac{1}{\bar{c}_A} \sum_{k=1}^m c_{A,k} u_{A,k} = \sum_{k=1}^m x_{A,k} u_{A,k} \quad [6]$$

where  $x_{A,k}$  is the molar fraction of the ionic species  $k$ .

The molar fractions of the ionic species are dependent on pH, so the effective mobility of the weak electrolyte is dependent on the pH of the solution as well. This fact shows that changing pH is a very powerful tool that allows one to ‘tune’ the effective mobilities of analytes to obtain their best separation.

## Other Ways to Influence Electrophoretic Mobility

As the difference in electrophoretic mobilities of analytes is of key importance for obtaining good separation, additional ways are used to influence it.

Here, electrophoresis often employs principles used in chromatography – interaction of the separands with another phase, which is called the pseudostationary phase. The pseudostationary phase is a substance that is added to the separation system in the column, and can interact with the species to be separated. The substance can be neutral, then it does not have its own electrophoretic movement; or it can be charged, then it can move in the column with certain mobility. In both cases, the analytes with their own electrophoretic movements encounter on their way the molecules of the pseudostationary phase and interact with them by forming a temporary complex or by association. During the time when the separands are bound to the pseudostationary phase its mobility is different; however, when it is free it moves with its own mobility. As the rate constants of the interaction are mostly very high, in analogy with weak electrolytes, the analyte then moves with a certain mean mobility that lies somewhere between the bound and free mobilities. The mean mobility is in this way dependent on the interaction (complexation) constant. Many substances can be used for this purpose, such as 2-hydroxyisobutyric acid, which forms complexes with many ions, especially with lanthanides, and enables their electrophoretic separation when added to the separation systems.

## Enantioselective Electrophoresis

An important task that can be solved by electrophoresis is the separation of enantiomers of chiral compounds. It is performed by means of their different interactions with a chiral pseudostationary phase – another chiral substance, called chiral selector, which is present in the separation system. The enantiomers of a chiral analyte have the same physicochemical properties in the achiral environment, so their mobilities are also the same and cannot be separated when the separation system is achiral. However, when a chiral substance, which is able to interact (to form complexes) with the analyte, is added to the system, the constants of complexity are generally different and the mobilities of the complexes with both enantiomers may also be different. This enables their separation.

## Micellar Electrokinetic Chromatography

In micellar electrokinetic chromatography (MEKC), the added pseudostationary phase are micelles. The micelles are spherical aggregates of several molecules of a surface-active compound like sodium dodecyl sulfate (SDS). The core of the SDS micelles is composed of entangled aliphatic chains, while the outer shell is formed by charged sulfate groups.

The micelles are highly charged and move in the electric field. They can interact with molecules of analytes, even when they are neutral, and form transient associations. In this way the analytes obtain an electrophoretic movement and can be separated if their interaction constants are different.

### Mobility in Sieving Media: Gel Electrophoresis

The hydrophilic gel soaked with an electrolyte solution, which is often used in electrophoresis as a supporting medium has, additionally, an even more important function: it serves as a sieving medium for separation of high molecular mass biomolecules such as DNA or proteins according to their chain length or molecular size. For example, in sequencing of DNA by the Sanger method the resulting mixture contains a series of single-stranded DNA fragments with the chain lengths ranging from  $\sim 20$  to  $600\text{--}1000$  nucleotides differing only by a single nucleotide. As every nucleotide contains a phosphate group, which has a negative charge, the total charge of any fragment is exactly proportional to its length. Such a mixture of chains cannot be separated by electrophoresis in simple liquid solutions according to their length. The reason is that the chains are only slightly coiled and form the statistical free-draining coils – that is, the electrolyte solution can flow through the coils. Thus, both the Coulombic force and the friction force are proportional to the chain length in the same way, and hence the mobility of the fragments in free solution  $\mu^0$  is not dependent on the chain length. The free solution mobility of DNA is  $\sim 37 \times 10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$  at  $25^\circ\text{C}$ . The free solution mobility was independent of DNA molecular mass, from  $\sim 400$  bp to  $48.5$  kbp.

The diameter of the DNA coils can be characterized by the gyration diameter  $R_g$ , which is dependent on the length of the chain. When the separation system is formed by a neutral cross-linked hydrophilic gel, e.g., polyacrylamide, with a certain mean size of pores between polymer chains, the separated DNA fragments being rather spherical coils mechanically collide with the polymer chains and have to pass through the pores in some way. When the polymer chains are approximately regarded as straight long rods with radius  $r$ , such a type of movement of the DNA fragments is called the Ogston movement. Its effective mobility  $\bar{\mu}$  is given by

$$\bar{\mu} = \mu^0 \exp(-K_R \Phi) \quad [7]$$

where  $K_R \sim (R_g + r)^2$  is the retardation coefficient and  $\Phi$  is the concentration of the gel. As the gyration

radius is dependent on the chain length, the effective mobilities of the DNA fragments are also dependent on the chain length. Thus, DNA fragments can be separated by electrophoresis.

The DNA fragments and also other biopolymers (proteins, carbohydrates) can be separated by electrophoresis in sieving media even if their chains are much longer and their gyration radius is much greater than the radius of pores. Here, other more complex mechanisms of movement play a role: reptation model (the separated molecule creeps in chains of the sieving medium as a reptile in grass), biased reptation model, biased reptation with fluctuation, model of entropic barriers, and geometration. For very long double-stranded DNA fragments (longer than  $\sim 10$  kbp) pulsed field gel electrophoresis is used, a technique that adopts alternating driving electric field. Here, the mode of movement of the chains is even more complicated.

### Theory – Continuity Equation

A simple environment, in which the separation process in electrophoresis takes place, allows easy formulation of basic transport laws that describe electromigration with good exactness and enables the separation process to be understood well. For example, the approximate continuity equations that describe electromigration of  $n$  strong ions in free solution are

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial x^2} + j \frac{\partial}{\partial x} \left( \frac{c_i u_i}{\kappa} \right), \quad i = 1, \dots, n \quad [8]$$

where  $D_i$  is the diffusion coefficient of the  $i$ th ion. These equations are able to provide information about the concentration of all  $n$  ions in the electric field in any time  $t$  and at any position  $x$  of the separation column, when the initial distribution of all ions is known. The first term on the right-hand side of eqn [8] describes diffusion and the second one electromigration. The division in the electromigration term is a nonlinear mathematical operation. This indicates that electromigration is intrinsically a nonlinear process. The nonlinearity is responsible for some phenomena in electrophoresis, such as self-sharpening of boundaries between zones of analytes or electromigration dispersion.

### Modes of Electrophoresis

The configuration of electrolytes in the separation system can substantially influence the electrophoretic separation. Some of the configurations or modes of electrophoresis showed to be well suited for

specific classes of analytical tasks and are now widely used. Here belong predominantly: zone electrophoresis, isotachopheresis (ITP), and isoelectric focusing (IEF).

### Zone Electrophoresis

This mode is characterized by two features: (1) the whole separation system together with electrode vessels is filled with a homogeneous solution of electrolytes, which is called the background electrolyte (BGE), (2) the mixture of analyzed species to be separated is introduced or injected in a rather low amount as a short plug at one end of the separation column (Figure 3). The mode of zone electrophoresis is often used in capillary columns, when it is called capillary zone electrophoresis (CZE). The BGE is mostly formed by a suitable buffer to maintain a certain pH, which is optimal for the separation of a given mixture. This mode is also almost exclusively used for gel electrophoresis: here the whole separation system is formed by a buffer-soaked hydrophilic slab gel and the mixture to be separated is introduced in little amounts at one end. After applying the driving electric field the analytes migrate in the column or in the slab gel with mutually different velocities so that they are spatially separated. After some time they are detected with a suitable detector located near the second end of the separation column; in the case of the slab gel electrophoresis, the plate with the gel is removed from electricity and the separated analytes are visualized as spots by a suitable reagent. The conductivity of the BGE in the separation system is only slightly influenced by the presence of the separated analytes, if their amount is low enough. Then, the  $\kappa$  in the denominator of the second term in eqn [8] is practically constant in time and homogeneous across the column length so that the

equations can be regarded as linear. The individual zones of analytes, although narrow at the beginning, become broader when moving in the column as diffusion causes their dispersion and their longitudinal profile attains a Gaussian shape. If, however, the amount of an analyte is rather high, it influences conductivity in its own zone, so it is no longer constant. Then, the nonlinearity arising in this way causes the electromigration dispersion – another type of broadening of the zones that further deforms zones to the triangular shape (Figure 4). The quantitative determination of a particular analyte is performed by integration of its detector signal.

### Isotachopheresis

ITP is used for separation of smaller species like inorganic or organic ions. The separation system, which serves for separation of either cations or anions, is composed of two different electrolyte solutions. The main features of ITP are as follows: (1) one electrode vessel and the separation column are filled with the leading electrolyte, whose cation (anion) has higher mobility (in absolute value) than any cation (anion) of the separated mixture; (2) the second electrode vessel is filled with the terminating electrolyte, whose cation (anion) has lower mobility than any cation (anion) of the separated mixture; (3) a plug of mixture of cations (anions) to be separated is introduced between the leading and terminating electrolytes (Figure 5). After applying the driving

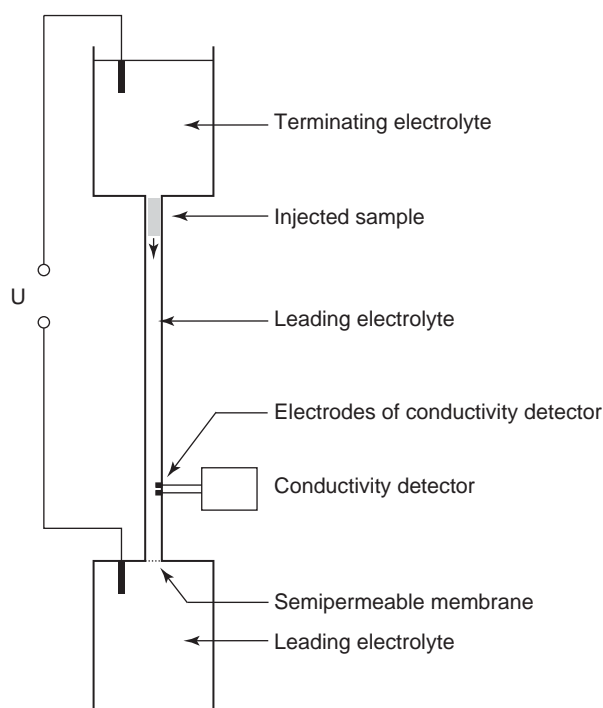

**Figure 3** Configuration of capillary zone electrophoresis. The arrangement shown is close to a real instrument. The capillary is often made of fused silica, whose typical length is 10–100 cm. It has an inner diameter of 20–100  $\mu\text{m}$  and its hydrodynamic resistance is rather high. The electroosmosis is allowed to flow. A photometric (UV) absorption detector is generally used.

**Figure 4** Longitudinal profiles of analytes in CZE as calculated from eqn [8] by computer. Background electrolyte: 20  $\text{mmol l}^{-1}$  acetic acid/10  $\text{mmol l}^{-1}$  potassium. Sample introduction: 2 mm plug of mixture of 1  $\text{mmol l}^{-1}$   $\text{Cs}^+$ , 1  $\text{mmol l}^{-1}$   $\text{Na}^+$ , 1  $\text{mmol l}^{-1}$   $\text{Li}^+$  ions, injected at position of 7 mm. Current density  $j = 200 \text{ A m}^{-2}$ . The picture shows resulting profiles at  $t = 250 \text{ s}$ , when all ions are almost separated. A slight triangular deformation of analyte zones caused by electromigration dispersion is obvious in the figure.

**Figure 5** Configuration of capillary isotachopheresis. The arrangement shown is close to a real instrument. The capillary is often made of plastic. The semipermeable membrane prevents electroosmotic and hydrodynamic flows of the electrolyte but allows electromigration of ions. A conductivity detector is often used. It has miniature electrodes placed inside the capillary.

electric field the ion of the leading electrolyte leaves the separation column and ‘pulls’ the sample ions, while the terminating ion starts to fill the column and ‘pushes’ the ions. The plug of the separated ions moves ‘bracketed’ between the leading and terminating electrolytes and every ion forms its own individual zone after some time. This stage is called the stationary state. All the zones of the ions are then stacked one by one and move with the same velocity, which is given by the velocity of the leading ion. Unlike the mode of zone electrophoresis, here the specific conductivities  $\kappa$  of the zones of the separated analytes are different and no longer constant. The nonlinearity in ITP is responsible for a useful phenomenon: ‘sharpening’ of the boundaries between the individual zones. The boundaries are very steep and the longitudinal profile of the zones of the analytes is almost rectangular (**Figure 6**). When the zones pass a detector located near the second end of the separation column, the detector gives a rather stepwise signal. The concentration of the analytes in their zones is not the same, as it was in the original mixture: it attains a certain value. For singly charged univalent ions or strong multicharged ions it can be derived from a simple relation, which is called the Kohlrausch regulating function. As concentrations of

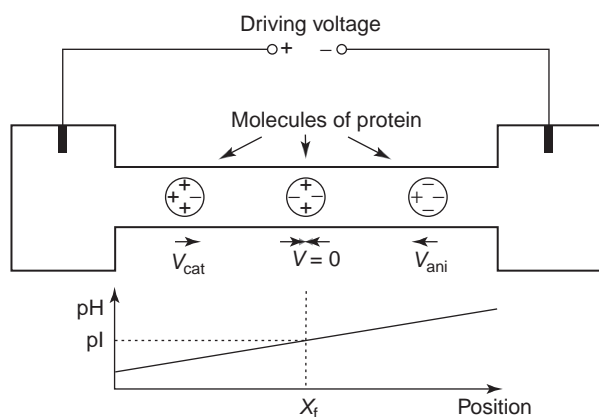

**Figure 6** Longitudinal profiles of analytes in capillary isotachopheresis as calculated from eqn [8] by a computer. Leading electrolyte:  $20 \text{ mmol l}^{-1}$  acetic acid/ $10 \text{ mmol l}^{-1}$  potassium. Terminating electrolyte:  $20 \text{ mmol l}^{-1}$  acetic acid/ $10 \text{ mmol l}^{-1}$  ammediol. Sample introduction:  $6 \text{ mm}$  plug of mixture of  $5 \text{ mmol l}^{-1}$   $\text{Na}^+$ ,  $5 \text{ mmol l}^{-1}$   $\text{Li}^+$  ions, injected at position of  $7 \text{ mm}$ . Current density  $j = 75 \text{ A m}^{-2}$ . The picture shows resulting profiles at  $t = 650 \text{ s}$ , when sodium and lithium are separated. They form isotachophoretic zones with virtually rectangular profiles stacked one by one.

the analytes in the ITP zones are fixed, the longitudinal length of the zone is directly proportional to their amount. The proportionality enables a precise quantitative determination of the analytes when measuring the length of their zones.

Interestingly, the principle of ITP is applied in the initial phase of disc electrophoresis, in the sample and stacking gels, for the purpose of sorting and concentrating (often by a factor of 10 000) the various protein zones. The ITP process is disrupted as the train of zones enters the running gel, where migration continues in the zonal mode.

### Isoelectric Focusing

IEF is an electrophoretic technique for separation of amphoteric species, mostly proteins. It is a technique based on differences in isoelectric points (pI). The species are separated in the pH gradient that is formed in the separation system. The pH gradient is generated in stabilizing matrices of special gels with proteolytic groups, mostly in slabs. Alternatively, it can be generated in a free solution without the gel by passing the electric current through the mixture of a series of ampholytes having isoelectric points in close proximity to each other. The analyte migrates in the separation system by electrophoretic movement according to its net charge. When it reaches a position where the pH is equal to its pI, the net charge becomes zero and the movement stops. The separated

**Figure 7** Principle of isoelectric focusing. The protein has cationic or anionic movement at pH which is below or above its pI, respectively. The velocity of the movement is zero, when protein reaches the position  $x_i$ , this is the site where it will be focused.

species are in this way focused at pH positions corresponding to their pI (Figure 7). When the slab gel is used, they are visualized by a suitable reagent; when focused in free solution in the column, the content of the column is pushed out by pressure or by changing electrolytes in the electrode vessels and detected by a detector located at the end.

## Electroosmotic Flow

The electroosmotic flow (EOF) is an electrokinetic phenomenon accompanying almost all electrophoretic methods. It arises due to the existence of the electric double layer at the inner surface of the separation channel. The electric double layer is generally formed at the interface between the liquid and solid phases. A possible specific adsorption of some ions from the liquid phase at the solid phase or dissociation of some ionogenic groups from the surface layer of the solid phase causes a layer of a surface charge, the Helmholtz layer, sticking to the channel inner wall. This is compensated by the opposite charge, which is distributed in the adjacent liquid solution of the BGE and which ranges to some distance from the inner wall. This part of the double layer is called the diffuse layer. The diffuse layer, which has an excess of volume charge, can be regarded as a very thin 'sleeve' of charged liquid adjacent to the inner wall. When the driving electric field is applied longitudinally to the channel axis, the Coulombic force acting at the charged 'sleeve' causes its movement. Due to friction forces the movement is, in very short time ( $10^{-4}$ – $10^{-2}$  s), spread over the whole volume of the channel and as a result the whole volume of the liquid flows in the channel. This

is the EOF. Unlike the electrophoretic movement where only charged species move in the separation system and neutral molecules of the solvent have no net movement, the EOF causes the liquid to move as a whole. In fact, it acts as a pump transporting a liquid from one electrode vessel to another. The EOF in itself cannot separate the analytes but it is vectorially superposed to its electrophoretic movement. The total electromigration velocity  $v_{EM,i}$  of the  $i$ th separated species is

$$v_{EM,i} = v_i + v_{EOF} \quad [9]$$

The EOF is especially important in CZE and MEKC. Here, the columns are often made of fused silica, and have negative charge at the inner wall due to dissociation of the silanol groups, which causes the EOF to flow in the direction of the cathode. Therefore, the electrophoretic movement of cationic species is speeded up, while the negative species move slower as the EOF flows against them. Sometimes the latter cannot reach the detector.

The distribution of the velocity of the EOF across the radius of the channel or column is an important issue. In the 'normal' laminar flow that is raised by a difference in pressure, the radial profile of the velocity vector has a parabolic shape: it is zero at the inner wall and maximum in the channel axis. The radial profile of the EOF is quite different: it is also zero at the wall but in a very short distance, which is approximately equal to the thickness of the diffusion layer, it attains a certain value, which is constant across the rest of radius. The radial profile of the EOF is 'plug-like'. This is a very beneficial feature of this type of flow, as it does not cause axial dispersion of the separand.

The excess of the volume charge in the diffuse layer causes the origin of the electric potential  $\phi(y)$  in liquid solution. It is dependent on the distance  $y$  from the Helmholtz layer (Figure 8). The potential  $\phi$  is conventionally set zero at a big distance from the wall. The value of the potential in the diffuse layer in the closest vicinity to the Helmholtz layer ( $y = 0$ ) is called the zeta potential,  $\phi(0) = \zeta$ . When longitudinal driving electric field  $E$  is applied, the velocity  $v_{EOF}$  of the plug-like EOF is related to the zeta potential by the Helmholtz–Smoluchowski equation:

$$v_{EOF} = -\frac{\varepsilon\zeta}{\eta} E \quad [10]$$

where  $\varepsilon$  is the permittivity and  $\eta$  is the dynamic viscosity, respectively, of the liquid solution. The zeta potential and, consequently, also the velocity of the EOF strongly depend on the quality of the surface. Various materials have different zeta potentials.

**Figure 8** Course of electric potential in the diffuse layer of  $10 \text{ mol dm}^{-3}$  NaCl. The zeta potential is supposed to be 100 mV. The curve is a solution of the Poisson–Boltzmann equation and is approximately exponential.

As pointed out above, fused silica used as a material for separation columns in capillary electrophoretic methods has normally a negative charge. Various ions, especially surfactants or big amphoteric ions, can be, however, adsorbed on the surface, which dramatically influences the zeta potential. For example, the addition of a small concentration of a suitable cationic surfactant like tetradecyltrimethylammonium bromide to the BGE causes its adsorption at the inner capillary wall and the reversal of the EOF in silica capillaries to the anodic side. Such surfactants are

often used in the separation of negatively charged species as the EOF in the anodic direction speeds up their movement. The EOF can be also utilized for pumping liquids in electrophoretic methods, especially in electrophoresis in chips. Further, it is used for pumping of the mobile phase in capillary electrochromatography. This method is a hybrid between electrophoresis and chromatography. Instead of using a mechanical pump for the transport of a liquid phase through the column it utilizes the EOF raised by the driving voltage.

## Introduction

Capillary isotachophoresis began to develop as a modern instrumental analytical method at the end of the 1960s and the beginning of the 1970s and is now a well-established method with a good theoretical background and available commercial instrumentation directed nowadays toward miniaturization. It is

highly useful for analysis of complex mixtures in solution, from simple inorganic ions up to proteins. Isotachophoresis (ITP) can be performed, however, also in any apparatus developed for capillary zone electrophoresis (CZE), and the advantages of this powerful analytical method can be employed in an effective online hyphenation with CZE or transiently within zone electrophoretic migration as well. Here, the basic theory, instrumentation, principles of qualitative and quantitative analyses, and examples of applications of single analytical ITP as well as combined techniques are described. The article is oriented to capillary ITP since capillaries provide high separation efficiency and speed of analysis; however,

the principles described here hold also for the performance in large bore tubes or flat beds.

## Principles

In ITP, the sample is injected between two electrolytes differing in the mobility of the ion that migrates in the same direction as the analytes do and are named the leading and terminating ions. The ion that migrates in the opposite direction is common for both electrolytes and is named the counterion. The common name for such an arrangement of electrolytes is the discontinuous electrolyte system. In a simplified case, i.e., if only strong electrolytes are considered, the leading electrolyte contains the leading ion with the highest mobility, whereas the terminating electrolyte contains the terminating ion with the lowest mobility in the isotachopheretic system. The mobilities of the sample ions should lie between those of the leading and the terminating ions. For weak electrolytes, similar criteria and actual effective mobilities, see below, must be applied.

Figure 1 shows a scheme of an isotachopheretic separation of a mixture of anions. The initial conditions, where the sample containing ions X and Y, e.g., periodate and iodate, respectively, is injected between the leading and terminating electrolytes, are depicted in Figure 1A. The leading electrolyte contains a leading ion L and a counterion, R, e.g., chloride and histidine, when a buffering system of

hydrochloric acid and histidine is used as the leading electrolyte. The terminating electrolyte contains a terminating ion, T, e.g., aspartate, which is suitable for the mentioned separation of periodate and iodate. After the current is switched on, the counterion R of the leading electrolyte (protonated histidine) moves toward the cathode and becomes the common counterion for the whole system. The sample, i.e., the mixed zone of anions periodate and iodate, moves toward the anode and separation occurs. The original mixed zone becomes shorter and shorter (Figure 1B) and then disappears. Thus, complete separation is reached as well as the steady state where all the anions move toward the anode in separate zones (Figure 1C).

The fundamental properties of an isotachopheretic system can be described as follows:

1. The zone of any ion of a substance X, which migrates in an isotachopheretic way behind the zone of L, migrates with the same velocity as the leading zone L,

$$v_{\text{iso}} = v_T = v_X = v_L \quad [1]$$

$$v_{\text{iso}} = \bar{u}_T E_T = \bar{u}_X E_X = \bar{u}_L E_L \quad [2]$$

where  $v_{\text{iso}}$  is the isotachopheretic migration velocity,  $v_X$  is the migration velocity of a zone X,  $\bar{u}_X$  is effective mobility of a substance X, and  $E_X$  is intensity of electric field in a zone X. The effective mobility of a given substance is of key importance here and is defined as follows. A substance X present in a solution in the form of species ions or neutral molecules  $X_0, X_1, X_2, \dots, X_n$  with ionic mobilities  $u_0, u_1, u_2, \dots, u_n$ , migrates in the electric field as a single substance with the effective mobility  $\bar{u}_X$  given by

$$\bar{u}_X = \frac{1}{\bar{c}_X} \sum_{i=0}^n c_i u_i \quad [3]$$

where  $\bar{c}_X$  is the total (analytical) concentration of the substance,

$$\bar{c}_X = \sum_{i=0}^n c_i \quad [4]$$

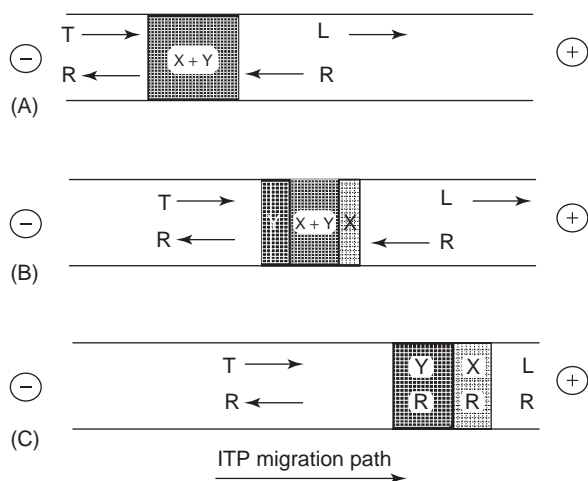

The equation defining  $\bar{u}_X$  can be rewritten in the form

$$\bar{u}_X = \sum_{i=0}^n \alpha_i u_i \quad [5]$$

where  $\alpha_i$  is the mole fraction of species  $X_i$ .

2. ITP proceeds in a channel of a constant cross-section  $S$ . Thus, the driving current density is constant along the whole path,

$$i = \frac{I}{S} = E_T \kappa_T = E_X \kappa_X = E_L \kappa_L \quad [6]$$

**Figure 1** Scheme of the separation process in anionic isotachopheresis of a mixture of anions X and Y. (A) initial conditions, the sample containing anions X and Y is injected between the leading electrolyte composed of the leading ion L and the counterion R, and the terminating electrolyte, containing the terminating ion T and the counterion R. (B) The formation of pure X and Y individual zones. (C) Final steady-state ready for detection of pure X and Y zones containing the entire quantity of sample anions.

where  $I$  is current and  $\kappa_X$  is the electrical conductivity in a zone  $X$ .

3. The boundaries between individual isotachopheretic zones are sharp – they exhibit self-sharpening effect. For any moving boundary  $2 \rightarrow 1$ , for which  $|\bar{u}_2| < |\bar{u}_1|$ , it holds also  $\kappa_2 < \kappa_1$  and from the relationship given in eqn [6] it follows that  $E_2 > E_1$ . It means that if an ion  $Y$  of lower mobility, e.g., iodate, enters due to diffusion the zone of faster ions  $X$  of periodate, its migration velocity  $v = E_Y \bar{u}_Y$  decreases to  $v = E_X \bar{u}_Y$ , and as a result the iodate ion is again caught up by its own zone. In contrast, if periodate ion appears in the zone of iodate with higher intensity of electric field, it is accelerated and pushed forward to join again the zone of periodate ions. Thus, the step change of intensity of electric field in zones ensures that the boundaries between individual zones remain sharp and physical parameters of the zones, e.g., concentration, conductivity, potential gradient, absorbance, and temperature change also stepwise as demonstrated in Figure 2.
4. The concentrations of substances in their own isotachopheretic zones are adjusted according to the composition of the leading zone, as also illustrated in Figure 2. The situation may be advantageously described with the help of the well-known regulating function derived by Kohlrausch in 1897 for uni-univalent strong electrolytes. Later, the Kohlrausch regulation function was redefined also for strong mono- and multicharged strong electrolytes, and singly charged weak electrolytes within the pH range 3–9. The value of the Kohlrausch regulation function is given by the composition of the original electrolyte along the migration path prior to onset of electromigration, i.e., before the current is switched on:

$$\omega(x) = \sum_i \frac{c_i(x) |z_i|}{|u_i|} = \text{const} (x) \quad [7]$$

where  $z_i$  is the relative charge and  $|u_i|$  is the absolute value of ionic mobility of the  $i$ th ionic species present at the given point  $x$ . The value of  $\omega(x)$  is retained after the current is switched on and remains constant at a certain point  $x$  during the electromigration. If step changes of  $\omega(x)$  occur in the electrolyte composition along the migration path prior to electromigration, then the concentrations of the migrating substances vary during electromigration so that the value of  $\omega(x)$  stays constant. The number of values of Kohlrausch regulation function along the migration axis corresponds to the number of phases (zones) that were in the system before electric current started

**Figure 2** Features of isotachopheretic zones. (A) Distribution of ion concentration along the migration path before isotachopheretic separation. (B) Distribution of ion concentration along the migration path after the isotachopheretic steady-state was reached. The concentrations of sample ions  $X$  and  $Y$  as well as of terminating ions are adjusted according to Kohlrausch regulation function. (C) Distribution of concentration,  $c$ , intensity of electric field,  $E$ , and inverse value of specific conductivity,  $1/\kappa$ , as detected with a detector placed as shown in scheme B. The height of an isotachopheretic step in the record,  $h_X$ , is the qualitative parameter reflecting the effective mobility of the ion migrating in its zone, the length of the isotachopheretic step,  $l_X$ , corresponds to the analyte amount in the sample and is the quantitative parameter. (D) Changes of absorbance followed with an optical detector placed as shown in scheme B. The height of an isotachopheretic step in the record is given by the extinction coefficient of the analyte, the length of the isotachopheretic step,  $l_X$  (or area of the step), corresponds to the analyte amount in the sample and is the quantitative parameter.

to flow. For strong uni-univalent electrolytes, where the electroneutrality condition in the zones is valid in the form  $c_{R,L} = c_L$ ,  $c_{R,A} = c_A$ , the application of Kohlrausch regulation function to zones  $L$  and  $A$  gives the explicit equation for the calculation of the concentration of an ion  $A$  in its zone adjusted according to the composition of the

leading zone:

$$c_A = c_L \frac{u_A |u_L| + |u_R|}{u_L |u_L| + |u_R|} \quad [8]$$

Obviously, the adjusted concentration  $c_A$  is independent of the original concentration of A in the sample. As a result of the adjustment of the sample concentration, a diluted sample is concentrated or a concentrated one is diluted when passing through the stationary boundary. The concentration of diluted samples by this ITP effect is commonly named stacking, see also later.

## Qualitative and Quantitative Analysis

The above-mentioned adjustment of concentrations and the same velocity of all zones have serious consequences for the qualitative and quantitative analyses. Its principle is different not only from that of zone electrophoresis but also from that of common elution chromatographic techniques. Thus, the separation of substances and the analytical interpretation of records are specific to this technique. In **Figure 2C**, a draft of a record from a universal detector of the analysis of a mixture of two ions is shown. Response on y-axis corresponds to resistance in the zone when a conductivity detector is used or to potential gradient when a potential gradient detector is used. The step height  $h$  reflects the reciprocal value of the effective mobility of ions in their zone and represents the qualitative value. The step length corresponds to the time when the given zone passes through the detector and therefore is proportional to the zone size. The step length is thus the quantitative value. In **Figure 2D**, the same mixture is detected with an optical, i.e., a selective detector. The step height is proportional to extinction coefficient in this case; step length, or better the area of the step, corresponds to the amount of the analyte and is used for quantitative evaluation. When the zone length is too short to create the plateau in the record and an optical detector is used, then only peaks (called spikes) are registered. Both their height and area are proportional to the concentration of the analyte in its zone and quantitative evaluation is still possible.

The practical qualitative analysis means identification of the steps in the record. It is mostly based on comparison between the analysis of standard substances and of sample components under the same conditions. If the standard substance forms a step in the record that is different from all the step heights in the sample, then this substance is not present in the sample. If the step height for the standard is identical to that for one of the components, then this substance may be present in the sample. When simultaneous

recording is performed with a selective detector and a universal one, e.g., conductivity and ultraviolet (UV) detectors, two independent data values are obtained for a single zone. If these values for the analyte in the sample and the standard are the same then the substance is most probably present in the sample.

The practical quantitative analysis is based on measuring the zone lengths,  $l$ , see **Figure 2C** and **D**. In practice, the length of the step in the record is measured, and calibration graphs are employed. Calibration involves plotting the amount of the standard (in moles) against the step length of the given zone in the form

$$N_X = kl_X \quad [9]$$

where  $N_X$  is the amount of the substance X injected,  $l_X$  is the step length in the record, and the constant  $k$  includes the operational parameters of the analysis. In practice, a blank must always be run to reveal the isotachophoretic boundary between the leading and terminating electrolytes. Often even analytical grade reagents contain impurities that also form zones (e.g., sodium in potassium acetate) that can coincide with the analyte zones.

There is still one important item to be mentioned here. If too much of a sample is injected, then the separation is not completed prior to detection and transient mixed zones are detected and registered. Decrease in the sample amount shortens the mixed zone until complete separation is achieved prior to detection. There is, however, still a potential complication that stems from the existence of stable mixed zones, i.e., zones that contain nonseparable substances irrespective of the injected sample amount. These zones can be avoided only by using another electrolyte system that ensures sufficient separability of sample components, see later. Obviously, correct quantification assumes complete separation, i.e., the absence of mixed zones.

## Instrumentation

For single isotachophoretic separation, usually a capillary made from fused silica or a suitable organic polymer of 0.1–0.8 mm ID is used. The ends of the capillary are connected to electrode chambers containing leading and terminating electrolytes, and platinum electrodes for connecting the high-voltage source. The high-voltage source provides a constant direct current up to 500  $\mu$ A and voltage up to 20 kV. A semipermeable membrane placed at the connection of the capillary and the leading electrolyte in the electrode chamber prevents hydrodynamic flow of the electrolyte. The part of the capillary between the chamber with the leading electrolyte and the

injection point is filled with the leading electrolyte; the part between the injection point and the chamber with the terminating electrolyte is filled with the terminating electrolyte. The sample (usually 1–30  $\mu\text{l}$ ) is injected either by microsyringe or through the valve. A detector detects separated zones and a PC processes the response. The most frequent detectors used in ITP are universal conductivity or potential gradient detectors or selective optical detectors, such as UV absorbance detector. It should be mentioned that simple isotachopheretic separations can be performed also in instrumentation used for CZE. It should be stressed, however, that in these apparatuses usually the capillary is not separated from the electrode chambers with a membrane. This is the so-called open system and the electroosmotic flow, if present, influences the migration velocity and direction of analytes in contrast to the closed system where only dispersion of zones can be expected.

Coupling of two capillaries of wider and narrower diameter connected by a bifurcation block enables to

perform more sensitive analyses with high loads. The scheme is shown in **Figure 3A**. In the first capillary, separation of a larger volume of the sample occurs and bulk components are driven to the auxiliary electrode. The analysis of interesting analytes then proceeds online in the analytical capillary of narrower diameter. Thus, higher sensitivity is reached resulting from the fact that the same zone volume in the capillary of a narrower diameter is longer and thus migration through the detector is longer. The system of column coupling is also used in miniaturized systems on chips made from suitable organic polymers. **Figure 3B** shows a scheme for one of the arrangements used on chips. The same principle of arrangement can be used also for the hyphenation of ITP and zone electrophoresis. The only difference is that the analytical capillary is filled with a suitable background electrolyte (BGE) where analytes can migrate in the CZE mode.

## Electrolyte Systems and Separation

The key problem to obtain correct results in ITP both for qualitative and quantitative analysis consists in the selection of a suitable electrolyte system, in which the analytes are completely separated and form stable isotachopheretic zones. Electrolytes are selected on the basis of data on the effective mobilities of the relevant substances and on ways of changing these effective mobilities by employing variable factors, especially the pH and complexation reactions. This variation is based on the definition of the effective mobility  $\bar{u}$ , which permits calculation of the effective mobility of the substance under the given conditions in the presence of acid–base and complexation equilibria. The tabulated values of the effective mobilities for a series of tested electrolyte systems over a wide range of pH values of the leading electrolyte are very useful.

Basic rules for the selection of the electrolyte system are listed in **Table 1**.

The leading ion is usually a suitable fast ion of a completely dissociated substance, e.g., chloride (ionic mobility  $-79.1 \times 10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ ). The terminating ion is usually  $\text{H}_3\text{O}^+$  for cations or  $\text{OH}^-$  for anions, which must always form the last zone in the system (at least theoretically). If the terminating ion consisting of  $\text{H}_3\text{O}^+$  ( $\text{OH}^-$ ) is too slow (the electric potential gradient is too high), it is preferable to use another faster substance as the terminating ion having usually the effective mobility higher than  $10 \times 10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ . **Table 2** shows ionic mobilities and  $\text{pK}$  values of several cations and anions. The effective mobility can easily be calculated for the given pH of the milieu by using the eqn [3].

Analysis	Anionic	Cationic
Leading ion (3–20 mmol l <sup>-1</sup> )	Cl <sup>-</sup> , NO <sub>3</sub> <sup>-</sup>	K <sup>+</sup> , Na <sup>+</sup> , NH <sub>4</sub> <sup>+</sup>
Terminating ion	OH <sup>-</sup> or weak acid	H <sub>3</sub> O <sup>+</sup> or weak base
Counterion	Weak base with $pK_{BH} = pH_L \pm 0.5$	Weak acid with $pK_{HA} = pH_L \pm 0.5$
pH <sub>L</sub>	$pH \geq pK_{HA}(\text{analyte}) - 1$	$pH \leq pK_{BH}(\text{analyte}) + 1$

pH<sub>L</sub> = pH of the leading electrolyte.

**Table 2** Ionic mobilities and dissociation constants of some ions at 25°C

Ion	Ionic mobility (10 <sup>-9</sup> m <sup>2</sup> V <sup>-1</sup> s <sup>-1</sup> )	pK
H <sub>3</sub> O <sup>+</sup>	+ 362.5	
OH <sup>-</sup>	- 205.5	
K <sup>+</sup>	+ 76.2	
NH <sub>4</sub> <sup>+</sup>	+ 76.1	9.25
Imidazole	52	7.15
Na <sup>+</sup>	+ 51.9	
Ethanolamine (+ 1)	+ 44.3	9.49
Lithium	+ 40.1	
Creatinine	+ 33.1	4.89
Histidine (+ 1)	+ 29.6	6.04
o-Chloraniline	+ 25	2.66
Tetrabutylammonium	+ 16.9	
OH <sup>-</sup>	- 205.5	
Cl <sup>-</sup>	- 79.1	
Nitrate	- 74.1	
Sulfate (- 1)	- 52.0	
Sulfate (- 2)	- 82.9	1.92
Pyruvate	- 42.3	2.49
Lactate	- 36.5	3.86
Phosphate (- 1)	- 35.1	2.12
Phosphate (- 2)	- 61.5	7.47
Phosphate (- 3)	- 71.5	12.36
Methionine	- 29.3	9.34
Hippurate	- 26.1	3.7
HEPES	- 21.8	7.51
LeuGlyPhe	- 19.3	7.94

HEPES = *N*-(2-Hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid).

If the separated substances are weak bases or acids, proper selection of the pH of the leading electrolyte and pK<sub>a</sub> of the counterion such that the conditions given in the Table 1 are approximately fulfilled should ensure sufficient ionization. Examples of electrolyte systems for ITP are shown in Table 3.

Another problem is to determine whether the substance of interest forms a stable individual zone in the selected system, i.e., the composition and volume

**Table 3** Examples of electrolyte systems for isotachophoresis

pH <sub>L</sub>	Counterion	Terminating ion
<i>Anionic analysis</i>		
3.1–4.1	β-Alanine	Propionate
4.1–5.1	EACA	Pivalate

9.0–10.0	Ethanolamine	EACA
<i>Cationic analysis</i>		
3.2–4.2	Formate	H <sub>3</sub> O <sup>+</sup> (formic acid)
4.2–5.2	Acetate	H <sub>3</sub> O <sup>+</sup> (acetic acid)
5.7–6.7	MES	Histidine
6.9–7.9	Veronal	Imidazole
8.3–9.3	Asparagine	Tris
9.1–10.1	Glycine	Triethanolamine
9.8–10.8	β-Alanine	Ethanolamine

Ammediol = 2-amino-2-methyl-1,3-propanediol; EACA = ε-amino-caproic acid; HEPES = *N*-(2-hydroxyethyl)piperazine-*N'*-(2-ethanesulfonic acid); MES = morpholinoethanesulfonic acid; TAPS = *N*-[tris(hydroxymethyl)methyl]-3-aminopropanesulfonic acid; TES = [tris(hydroxymethyl)methyl]-2-aminoethanesulfonic acid; Tris = tris(hydroxymethyl)aminomethane; Veronal = 5,5-diethylbarbituric acid.

of a zone do not change with time. Experimental verification of zone stability is very simple and consists in testing whether the calibration graph constructed for the substance passes through the origin. Theoretical considerations are based on effective mobilities; for the stable zone of a substance X it must hold

$$|\bar{u}_{T,T}| < |\bar{u}_{X,T}| \quad \text{and} \quad |\bar{u}_{X,X}| < |\bar{u}_{L,X}| \quad [10]$$

which means that the effective mobility of the substance X in the terminating zone,  $|\bar{u}_{X,T}|$ , is higher than the effective mobility of the terminator in its own zone,  $|\bar{u}_{T,T}|$ , and the effective mobility of the leading ion in the zone of the substance X,  $|\bar{u}_{L,X}|$ , is higher than the effective mobility of the substance X in its own zone,  $|\bar{u}_{X,X}|$ .

The third task is to verify whether the substances of interest are separable, i.e., whether they form their individual zones separated from each other. Experimental verification of the separability is simple but laborious and is based on measuring calibration graphs for standard solutions of individual substances and for their mixtures. For theoretical evaluation, it is not sufficient to compare the tabulated or calculated effective mobilities of the substances in their own zones (parameters of the  $\bar{u}_{i,i}$  type) since some pairs of substances of the same effective mobilities in their own zones can be completely separated

and migrate separately while other pairs of different effective mobilities in their own zones do not separate. It must be based on evaluation of separability of substances on the basis of parameters of  $\bar{u}_{i,j}$  (effective mobility of an analyte  $i$  in the neighboring zone  $j$ ) and is identical with the principle of unambiguous determination of the migration order of substances. If the migration order can be determined unambiguously for a pair of substances  $i$  and  $j$  in a given electrolyte system, then substances  $i$  and  $j$  can be separated. A simple criterion can be employed to evaluate separability based on the migration order. Two cases representing separation are possible:

1. the zone of a substance  $i$  migrates ahead of the zone of a substance  $j$  if

$$|\bar{u}_{i,j}| > |\bar{u}_{j,j}| \quad \text{and} \quad |\bar{u}_{j,i}| < |\bar{u}_{i,i}| \quad [11]$$

2. the zone of a substance  $j$  migrates ahead of the zone of a substance  $i$  if

$$|\bar{u}_{i,j}| < |\bar{u}_{j,j}| \quad \text{and} \quad |\bar{u}_{j,i}| > |\bar{u}_{i,i}| \quad [12]$$

If conditions [11] and/or [12] are not valid for a given pair of substances then a third case takes place where

$$|\bar{u}_{i,j}| < |\bar{u}_{j,j}| \quad \text{and} \quad |\bar{u}_{j,i}| < |\bar{u}_{i,i}| \quad [13]$$

Here, the migration order cannot be determined unambiguously and the two substances form a stable mixed zone and cannot be separated.

## Isotachophoretic Stacking and Combination ITP-CZE

### Single Capillary System

Arrangement for ITP, i.e., the discontinuous electrolyte system where mobilities of sample components are lower than the mobility of the leading ion, and higher than the mobility of terminating ion, is usually created prior to the separation in an instrumentation with a capillary where only a leading electrolyte, a terminating electrolyte, and a sample plug were injected, **Figure 4A**. Isotachophoretic stacking power, however, can also be used within zone electrophoretic separation. In such a case, the capillary is filled with a BGE of a constant composition and prior and after the sample plug, zones of leading electrolyte and terminating electrolyte of a proper composition and length are loaded, **Figure 4B**. If the co-ion of the

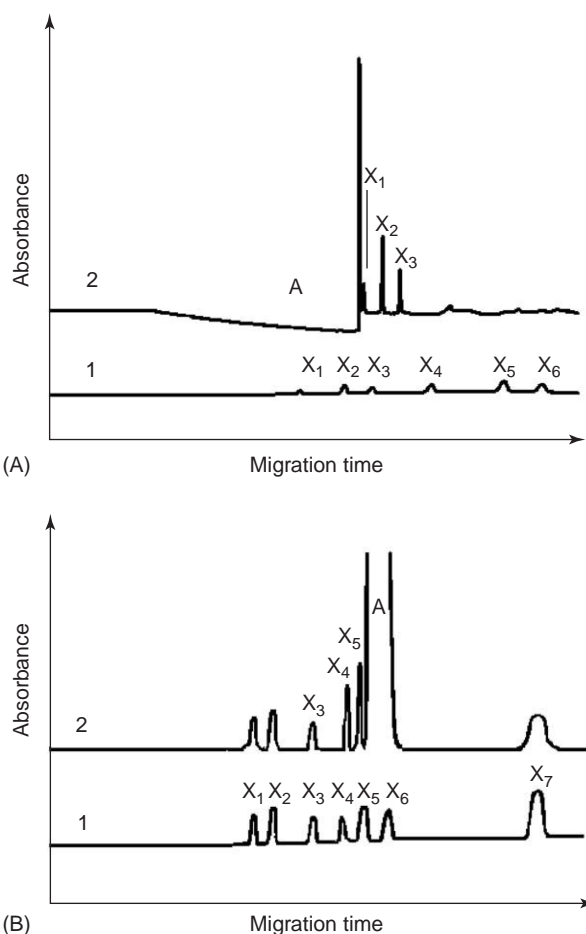

**Figure 4** Arrangement of discontinuous electrolyte systems for isotachopheresis. (A) The capillary is filled with the leading electrolyte containing a leading ion L, the sample plug X + Y is followed with the terminating electrolyte with a terminating ion, T. (B) The capillary is filled with a background electrolyte, BGE, then a plug of a leading electrolyte is injected followed with the sample plug and the plug of a terminating electrolyte. The end of the capillary is immersed again into the BGE solution. (C) As in B, but BGE plays the role of the terminating electrolyte and thus only a plug of a leading electrolyte has to precede the sample zone. (D) As in B, the BGE co-ion is the fastest in the system and ensures the role of the leading ion. The injection of the sample plug is followed with the injection of the zone of a terminating electrolyte prior the capillary is immersed into the solution of BGE. (E) The role of an isotachophoretic stacker is ensured by presence of a macrocomponent A in the sample. The stacker can be faster than analytes in the sample and plays then the role of the leading ion. The BGE co-ion has the function of the terminator. If the macrocomponent is slower than the analytes, it can act as the terminator and simultaneously, the BGE co-ion acts as the leading ion.

BGE is selected in such a way that it can play the role of a terminating ion for a sample, then only the zone of a suitable leader has to be injected in front of the sample zone, **Figure 4C**. Similarly, if the co-ion of the BGE can serve as a leading ion, then the sample plug is followed by the zone of terminator only and the separation proceeds, **Figure 4D**.

In all above cases, the ITP migration is only temporary and is called transient ITP. It has, however, great analytical significance. The great advantage of involving transient ITP into the CZE separation process is enhancement of sensitivity due to the isotachopheretic concentrating effect. The analytes present in the sample in low concentrations are stacked into narrow zones of the concentration corresponding to the Kohlrausch  $\omega$  function. As can be seen from **Figure 4E**, a suitable arrangement for transient ITP can arise also when the sample itself contains macrocomponents that can act as isotachopheretic stackers. When the BGE is constructed so that the co-ion can act as the terminator and a macrocomponent A present in the sample in a concentration higher than a minimum needed value can play the role of the leading ion for an analyte of interest, X, i.e.,  $|u_A| > |u_X| > |u_{BGE}|$ , see **Figure 5A**, or vice versa the BGE co-ion is the fastest ion in this transient ITP mode and acts as the leader and a macrocomponent has the role of the terminator, i.e.,  $|u_{BGE}| > |u_X| > |u_A|$ , see **Figure 5B**, the analyte is concentrated with respect to the concentration of the transient leader according to the Kohlrausch regulation function. This is a very frequent case in biological samples, where, e.g., a bulk concentration of NaCl ensures the presence of a fast ion possessing properties of the leader for both anions (chloride) and cations (sodium), and arrangement for transient ITP can simply be created by the proper choice of the composition of the BGE, especially as far as mobility and the concentration of the BGE co-ion are concerned. Analytes stacked during transient ITP between the leading type (terminating type) stacker and the BGE co-ion are leaving the ITP stack gradually. The analyte with the mobility closest to that of the stacker migrates in the ITP mode the longest and its zone is the sharpest, as can be seen also in **Figure 5**. In this case, a sufficiently long migration path is recommended to ensure destacking of all analytes from ITP mode and to obtain suitable resolution so as to employ also the advantage of CZE migration.

If more macrocomponents are present in a complex sample matrix, generally two different situations can be distinguished. First, macrocomponents can act as stackers of either leading or terminating type and the resulting effect is a sum of their stacking

**Figure 5** Illustration of isotachopheretic effect in CZE. (A) A macrocomponent present in the sample plays the role of the leading ion. Trace 1, analysis of six analytes of  $10^{-5} \text{ mol l}^{-1}$  concentration in a BGE with the mobility of the co-ion equal to that of the analyte  $X_4$ . Trace 2, analysis of the same sample containing a macrocomponent A with the mobility higher than that of the fastest ion  $X_1$  at the concentration  $10^{-2} \text{ mol l}^{-1}$ . Conditions for isotachopheretic stacking of analytes with mobilities  $|u_A| > |u_X| > |u_{BGE}|$  are ensured, the macrocomponent acts as the leader and BGE co-ion as the terminator, enhancement of analyte concentration in their zones reflects in sharpening the peaks. (B) A macrocomponent present in the sample plays the role of the terminating ion. Trace 1, analysis of seven analytes of  $10^{-5} \text{ mol l}^{-1}$  concentration in a BGE with the mobility of the co-ion equal to that of the analyte  $X_3$ . Trace 2, the concentration of the analyte  $X_6$  is increased to  $5 \times 10^{-3} \text{ mol l}^{-1}$ , conditions for isotachopheretic stacking of analytes with mobilities  $|u_{BGE}| > |u_X| > |u_A|$ , i.e., for  $X_4$  and  $X_5$  are ensured with the macrocomponent A acting as the terminator and BGE co-ion as the leader. The peaks of the isotachopheretically stacked analytes were sharpened, sensitivity was increased. (Reprinted with permission from *Journal of Chromatography A* (2001), vol. 916, p. 173. Copyright (2001), © Elsevier.)

effects. Second, one macrocomponent acts as the stacker (A) and the other one acts against stacking as the so-called destacker (B). This happens when  $|u_A| > |u_X| > |u_B| > |u_{BGE}|$ ,  $|u_A| > |u_X| > |u_B| = |u_{BGE}|$

or  $|u_A| > |u_X| > |u_{BGE}| > |u_B|$  in the leading type of stacking, and similarly for the terminating type of stacking when  $|u_{BGE}| > |u_B| > |u_X| > |u_A|$  or  $|u_{BGE}| = |u_B| > |u_X| > |u_A|$  or  $|u_B| > |u_{BGE}| > |u_X| > |u_A|$ , and simultaneously, the concentration ratio of the stacker to the destacker is lower than a critical value,  $c_A/c_B < a_{crit}$ , where for  $a_{crit}$  it holds

$$a_{crit} = \frac{|u_B| + |u_R|}{|u_A| + |u_R|} \cdot \frac{|u_A| - |u_X|}{|u_X| - |u_B|} \quad [14]$$

When  $c_A/c_B > a_{crit}$ , the stacker has a sufficient potential to ensure stacking of analytes the mobilities of which are lying between  $|u_A|$  and  $|u_B|$  (for  $|u_B| > |u_{BGE}|$  or  $|u_B| = |u_{BGE}|$ ) or between  $|u_A|$  and  $|u_{BGE}|$  (for  $|u_B| < |u_{BGE}|$ ) for the leading type of stacking and analogously in the reversed way for the terminating type of stacking. It should be stressed here that not only a sample macro component can act as the destacker but also the BGE co-ion when present in the sample acts against stacking.

### Column Coupling System

The instrumentation for column coupling arrangement has already depicted in **Figure 3A** and **B**. This arrangement offers not only stacking but also elimination of interfering bulk components, provided that suitable combination of electrolyte systems is used. The combinations of electrolytes for both capillaries in the ITP–CZE arrangement are shown in **Figure 6**.

The simplest is the first combination where the terminator from ITP step is used also as the BGE in the second step. In this configuration, the arrangement for the analysis is set completely before the analysis starts and the only task to do is to switch the voltage across the system of both capillaries (see  $E_1$  and  $E_3$  in **Figure 5A**) at a proper time. This prevents the loss of an interesting part of the sample by its migration to the auxiliary electrode in the reservoir of the leading electrolyte in the first capillary (see  $E_2$  in **Figure 5A**). In both hyphenations, ITP–ITP and ITP–CZE, the proper switching of current between

**Figure 6** Combination of electrolyte systems for the hyphenation of capillary isotachopheresis with zone electrophoresis in column coupling instrumentation. (A) T–S–T system, where the separation in the CZE step proceeds in the terminating electrolyte from the ITP step. A short zone of the leading electrolyte was allowed to enter the second capillary to avoid loss of sample components and responds for temporary survival of isotachophoretic mode of migration. The result is enhanced separation efficiency of faster sample components. (B) L–S–L system, where the separation in the CZE step proceeds in the leading electrolyte from the ITP step. A short zone of the terminating electrolyte was allowed to enter the second capillary to avoid loss of sample components and responds for temporary survival of isotachophoretic mode of migration. The result is enhanced separation efficiency of slower sample components. (C) BGE–S–BGE system, where the separation in the CZE step proceeds in a background electrolyte different from leading and terminating electrolytes. Short zones of leading and terminating electrolytes were allowed to enter the second capillary to avoid loss of sample components and respond for temporary survival of isotachophoretic mode of migration. The result is enhanced separation efficiency of faster and slower sample components.

electrodes  $E_2$  and  $E_3$  enables very precise cleaning of the sample resulting in a shorter time of analysis and more sensitive and reliable results.

## Applications

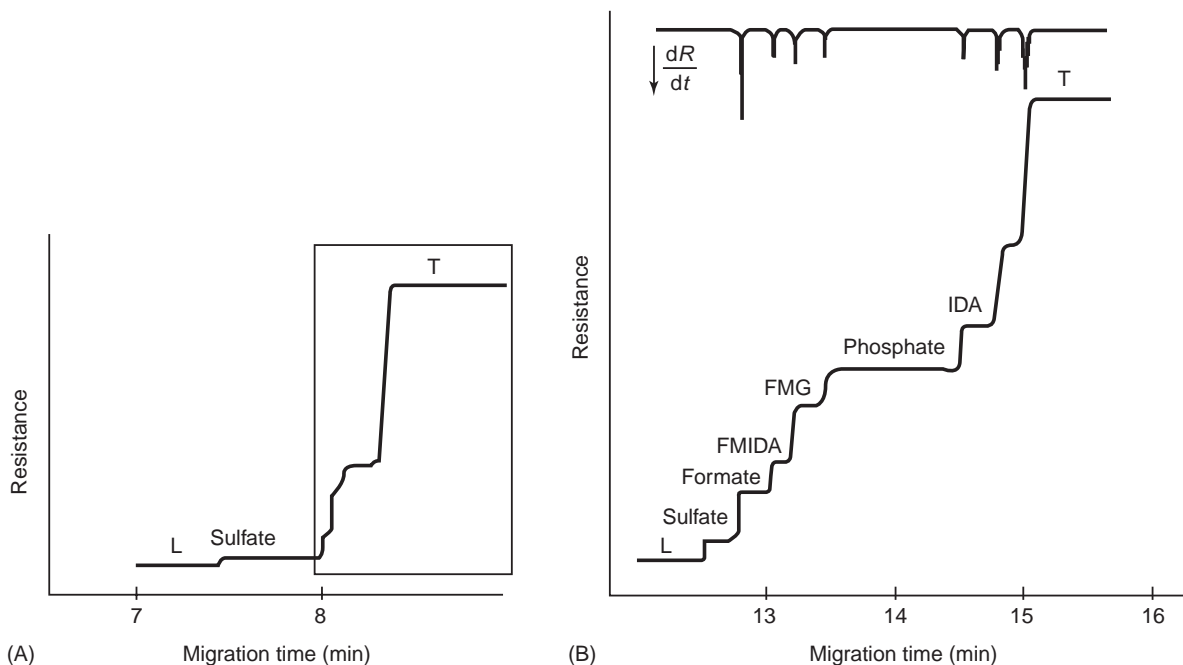

A basic characteristic of ITP is the limitation of its use to ionogenic substances. In a single run either anions or cations are analyzed; however, electrolyte systems that enable simultaneous analysis of both groups can be found and so called bi-directional ITP employing two detectors can be performed. Non-ionogenic substances that often form the bulk of a sample do not interfere with the analysis. Advantages of ITP include its independence of derivatization and deprotection of the sample and this feature can be very effectively evaluated when ITP is used as a pre-separation method. ITP is mostly carried out in aqueous solutions or in aqueous mixtures with solvents and therefore it is most useful for substances that are water-soluble or can be included into water-soluble complexes, e.g., with micelles of surfactants.

Most of the practical applications of ITP are found in the analysis of ionogenic organic substances,

especially in biochemistry, industrial chemistry, and environmental analysis, as reflected in the examples given below.

**Figure 7** demonstrates an analysis of 5  $\mu\text{l}$  of 100 times diluted mother liquor from the synthesis of herbicide glyphosate (*N*-phosphonomethylglycine). In **Figure 7A**, the record from the pre-separation capillary is shown and the part of the sample that is transferred to the second narrower capillary is denoted. The zone of sulfate is removed by migrating to the auxiliary electrode in the first step. For more precise reading of the step length, the recorded curve from the second capillary, **Figure 7B**, is differentiated and inflex points of the curve are read as distances between maxima of the differential record,  $dR/dt$ . The leading electrolyte was  $0.01 \text{ mol l}^{-1}$  HCl + histidine, pH 6.0, the terminating electrolyte was  $0.01 \text{ mol l}^{-1}$  morpholinoethanesulphonic acid (MES).

In **Figure 8**, an example of an isotachopheretic separation on a poly(methyl methacrylate) chip is shown demonstrating an analysis of organic acids and inorganic ions present in red wine. A 0.9  $\mu\text{l}$  (the fixed volume of the sampling channel) of 20 times diluted red wine was analyzed using of  $10 \text{ mmol l}^{-1}$

**Figure 7** ITP–ITP analysis of 5  $\mu\text{l}$  of 100 times diluted sample of the mother liquor from the synthesis of herbicide glyphosate (*N*-phosphonomethylglycine, FMG). (A) Preseparation capillary, ID 0.8 mm. The zone of sulfate is transported to the auxiliary electrode  $E_2$ , see **Figure 5**, and by proper timing of switching current between electrodes  $E_1$ – $E_2$ , and  $E_1$ – $E_3$ , the demarcated part is transferred to the second capillary. (B) The record from conductivity detector in the second capillary, ID 0.3 mm. For more precise reading of the step length, the recorded curve from conductivity detector is differentiated and inflex points of the curve are read as distances between maxima of the differential record,  $dR/dt$ . FMIDA, *N*-phosphonomethyliminodiacetic acid; IDA, iminodiacetic acid; L, leading ion (chloride); T, terminating ion (MES). The composition of electrolytes was: LE  $0.01 \text{ mol l}^{-1}$  HCl + histidine, pH 6.0, TE:  $0.01 \text{ mol l}^{-1}$  morpholinoethanesulphonic acid (MES). system,  $10 \text{ mmol l}^{-1}$  HCl +  $\beta$ -alanine, pH 4.2, was used as the leading electrolyte for the pre-separation stage, and  $5 \text{ mmol l}^{-1}$  HCl + glycine, pH 3.0, was used as the leading electrolyte for the analytical stage. A volume of  $10 \text{ mmol l}^{-1}$  nicotinic acid served as the terminating electrolyte.

In Figure 10, hyphenation of ITP with zone electrophoresis is demonstrated for an analysis of ascorbic acid in serum. Figure 10A shows the isotachopheretic step of a serum sample analyzed in the electrolyte system: leading electrolyte:  $10 \text{ mmol l}^{-1}$  HCl +  $\beta$ -alanine, pH 3.3; terminating electrolyte:  $10 \text{ mmol l}^{-1}$  propionic acid. Only components migrating behind lactic acid are driven to the second capillary filled with  $50 \text{ mmol l}^{-1}$  propionic acid adjusted with  $\beta$ -alanine to pH 3.8 (corresponding to the pH of terminating electrolyte adjusted according to Kohlrausch equation) serving as BGE for the CZE step. This is the combination of electrolytes denoted as T-S-T, cf. Figure 6. The record in Figure 10B shows an excellent reproducibility of migration time of two samples from different persons.

Figure 11 shows an analysis of a human serum by capillary zone electrophoresis with inherent transient isotachopheretic stacking of analytes. The excess of chloride present naturally in the sample acts as the stacker for analytes citrate, malate, and acetoacetate with mobilities lower than the mobility of the BGE co-ion, mandelate, in the BGE composed of  $5 \text{ mmol l}^{-1}$  mandelic acid +  $\epsilon$ -aminocaproic acid, pH 3.8. Lactate has lower mobility than the BGE co-ion; however, the predominating stacking effect of chloride eliminates its destacking effect.

**Figure 9** ITP-ITP analysis of  $5 \mu\text{l}$  of untreated heparin plasma of patients with diabetes mellitus. (A) The record from the conductivity detector in the pre-separation capillary, ID  $0.8 \text{ mm}$ , LE  $10 \text{ mmol l}^{-1}$  HCl +  $\beta$ -alanine, pH 4.2. (B) The record from the analytical capillary, ID  $0.3 \text{ mm}$ , LE  $5 \text{ mmol l}^{-1}$  HCl + glycine, pH 3.0. L, leading ion – chloride; T, terminating ion – nicotinate. ## Introduction

Isoelectric focusing (IEF) represents a unique electrokinetic method, in that it is based on steady-state patterns attained by amphoteric species (mostly proteins and peptides) along a pH gradient under the influence of an electric field. Amphoteric compounds migrate until they align themselves at their isoelectric positions, where a dynamic equilibrium is produced between electrokinetic concentrating processes and dispersive effects that include diffusion. Extremely sharp zones are thus obtained, characterized by a very high resolving power. We will deal with conventional IEF in soluble, amphoteric buffers and with immobilized pH gradients (IPG) in insolubilized, nonamphoteric buffers in gel media. Additionally, we will cover IEF in capillaries, the most recent evolution of this technique.

## Conventional Isoelectric Focusing

In principle, pH gradients could be obtained by diffusion of nonamphoteric buffers but such ‘artificial’ gradients would be altered by changes in electric migration and diffusion of the buffer ions. Thus, in 1961, Svensson introduced the concept of ‘natural’ pH gradients, created and stabilized by the electric current itself. The buffers used in this system required two fundamental properties: (1) amphotericism, so that they could reach an equilibrium position along the separation column and (2) ‘carrier’ ability. This latter concept is subtler but just as fundamental. Any ampholyte cannot simply be used for IEF; only a carrier ampholyte (CA), which is a compound capable of transporting the current (a good conductor) and capable of carrying the pH (a good buffer). With this notion, and with Vesterberg’s elegant synthesis of such ampholytes, present-day conventional IEF was born.

## Some Basic Theoretical Concepts

We will survey here some basic equations governing the IEF process. The most important one regards the distribution profile of an ampholyte about its

## Introduction

Isoelectric focusing (IEF) represents a unique electrokinetic method, in that it is based on steady-state patterns attained by amphoteric species (mostly proteins and peptides) along a pH gradient under the influence of an electric field. Amphoteric compounds migrate until they align themselves at their isoelectric positions, where a dynamic equilibrium is produced between electrokinetic concentrating processes and dispersive effects that include diffusion. Extremely sharp zones are thus obtained, characterized by a very high resolving power. We will deal with conventional IEF in soluble, amphoteric buffers and with immobilized pH gradients (IPG) in insolubilized, nonamphoteric buffers in gel media. Additionally, we will cover IEF in capillaries, the most recent evolution of this technique.

## Conventional Isoelectric Focusing

In principle, pH gradients could be obtained by diffusion of nonamphoteric buffers but such ‘artificial’ gradients would be altered by changes in electric migration and diffusion of the buffer ions. Thus, in 1961, Svensson introduced the concept of ‘natural’ pH gradients, created and stabilized by the electric current itself. The buffers used in this system required two fundamental properties: (1) amphotericism, so that they could reach an equilibrium position along the separation column and (2) ‘carrier’ ability. This latter concept is subtler but just as fundamental. Any ampholyte cannot simply be used for IEF; only a carrier ampholyte (CA), which is a compound capable of transporting the current (a good conductor) and capable of carrying the pH (a good buffer). With this notion, and with Vesterberg’s elegant synthesis of such ampholytes, present-day conventional IEF was born.

## Some Basic Theoretical Concepts

We will survey here some basic equations governing the IEF process. The most important one regards the distribution profile of an ampholyte about its

isoelectric point. Under steady-state conditions (as obtained by balancing the simultaneous electrophoretic and diffusional mass transports), Svensson, in 1961, derived the following differential equation describing the concentration profile of a focused zone:

$$C\mu/qk = D(dC/dx) \quad [1]$$

where  $C$  is the concentration of a component in arbitrary mass units per arbitrary volume unit;  $\mu$  the electrophoretic mobility in  $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$  of ion constituent except  $\text{H}^+$  and  $\text{OH}^-$ , with positive sign for cationic and negative sign for anionic migration;  $i$  the electric current in A;  $q$  the cross-sectional area in  $\text{cm}^2$  of electrolytic medium, measured perpendicularly to the direction of current;  $k$  the conductance of medium, in  $\Omega^{-1} \text{cm}^{-1}$ ;  $D$  the diffusion coefficient in  $\text{cm}^2 \text{s}^{-1}$  of a given ionic component with mobility  $\mu$ ;  $x$  the coordinate along the direction of current,  $x$  increasing from 0 at the anode to higher values toward the cathode.

Each term in eqn [1] expresses the mass flow per second and square centimeter of the cross-section, that on the left being the electric and that on the right the diffusional mass flows. If eqn [1] is written in the form:

$$(i\mu/q)(dx/k) = D(dC/C) \quad [2]$$

it is seen that it is possible to integrate it if  $\mu$  is known as a function of pH and  $D$  as a function of  $C$ . Specifically, if the conductance, the diffusion coefficient, and the derivative:

$$p = -d\mu/dx = -[d\mu/d(\text{pH})][d(\text{pH})/dx] \quad [3]$$

(where  $p$  is the ratio between the protein titration curve and the slope of the pH gradient over the separation axis) can be regarded as constant within the focused zone, then  $\mu = -px$  and one obtains the following analytical solution:

$$C = C_0 \exp[-(pix^2)/(2qkD)] \quad [4]$$

where  $x$  is now defined as being equal to zero at the concentration maximum  $C_0$ . This is a Gaussian concentration distribution with the inflection points at:

$$x_i = \pm\sqrt{(qkD)/(pi)} \quad [5]$$

where  $x_i$  denotes the width of the Gaussian distribution of the focused zone measured from the top of the distribution of the focused ampholyte to the inflection point (one standard deviation). The course of the pH gradient is  $d(\text{pH})/dx$  and  $d\mu/d(\text{pH})$  represents the titration curve of the ampholyte. It should be

borne in mind that this Gaussian profile holds only if and as long as the conductivity of the bulk solution comprised within the zone is constant. Constant conductivity along a pH gradient is quite difficult to maintain, especially as one approaches pH extremes (below pH 4 and above pH 10), if for no other reason, because the non-negligible concentration of  $\text{H}^+$  and  $\text{OH}^-$  present in the bulk liquid begin to strongly contribute.

Another important equation regards the resolving power in IEF, expressed in  $\Delta(\text{pI})$  units, i.e., in the minimum difference of surface charge between two adjacent proteins that the IEF technique is able to resolve. If two adjacent zones of equal mass have a peak-to-peak distance three times larger than the distance from peak to inflection point, there will be a concentration minimum approximating the two outer inflection points. Taking this criterion for resolved adjacent proteins, Rilbe has derived the following equation for minimally but definitely resolved zones:

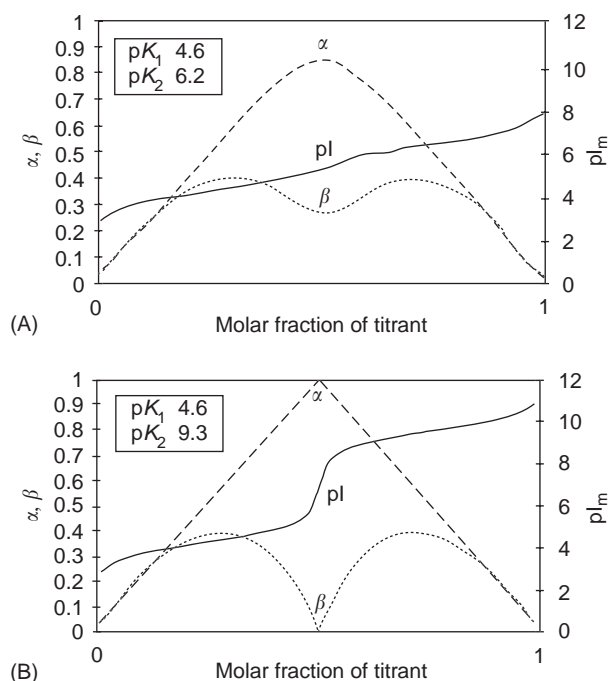

$$\Delta(\text{pI}) = 3\sqrt{\{D[d(\text{pH})/dx]\}/\{E[-d\mu/d(\text{pH})]\}} \quad [6]$$

Equation [6] shows that good resolution should be obtained with substances with a low diffusion coefficient ( $D$ ) and a high mobility slope  $[d\mu/d(\text{pH})]$  at the isoelectric point – conditions that are satisfied by all proteins. Good resolution is also favored by a high field strength ( $E$ ) and a shallow pH gradient  $[d(\text{pH})/dx]$ . It will be seen that, whereas in conventional IEF the limit to the resolving power is  $\sim 0.01$ , in IPGs it is 0.001 pH units.

### The Carrier Ampholyte Buffers

We recall here that the buffer capacity of an ampholyte in the isoprotonic state decreases with increasing  $\Delta\text{pK}$  across the isoprotonic point, linearly at first, then exponentially. Let us take as an example a hypothetical ampholyte, with  $\text{pK}_1 = 4.6$  (a carboxyl group) and  $\text{pK}_2 = 6.2$  (an amino group), having thus  $\text{pI} = 5.4$  and  $\Delta\text{pK} = 1.6$ . If we titrate this ampholyte in the pH 4–7 range, encompassing the two  $\text{pK}$ s, and if we plot the accompanying buffering power ( $\beta$ ), degree of dissociation ( $\alpha$ ), and slope of the pH gradient, we will have the plot of **Figure 1A**. It can be seen that there is still a substantial buffering power at the  $\text{pI}$  of the ampholyte, with a corresponding degree of ionization less than unity, and that the titration curve is smooth throughout the pH gradient explored, with only a small deviation about the  $\text{pI}$  of the ampholyte, indicating that this species is indeed a 'good' CA. Let us now take an ampholyte with  $\text{pK}_1 = 4.6$  but with  $\text{pK}_2 = 9.3$ , thus with a  $\text{pI} = 6.95$  and  $\Delta\text{pK} = 4.7$ . If we now titrate it in the pH 4–10 range, again encompassing the two  $\text{pK}$  values, we will have the graph of **Figure 1B**. It can be seen now

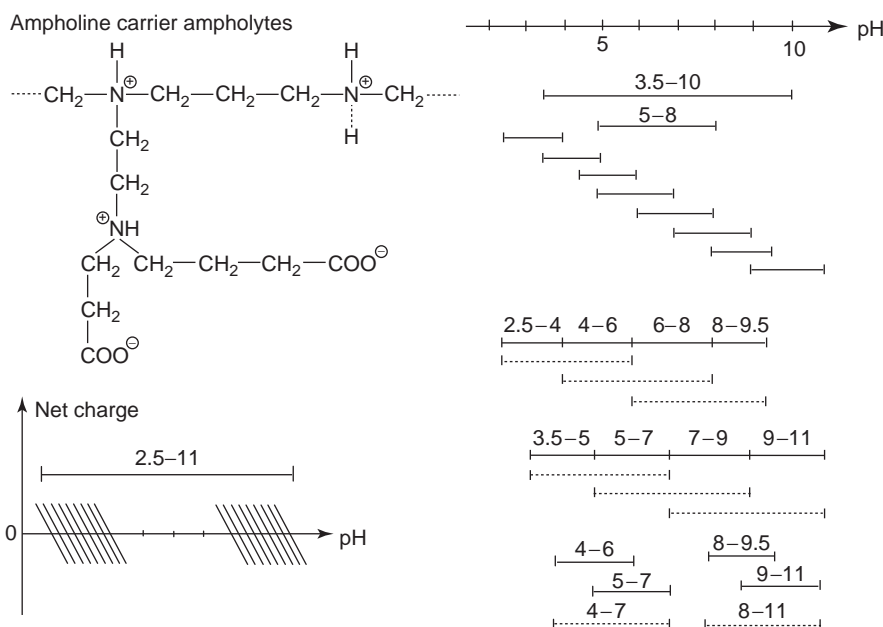

**Figure 1** Degree of ionization ( $\alpha$ ) and buffering power ( $\beta$ ) of a good (A) and a poor (B) carrier ampholyte. (A) Computer simulations obtained assuming  $pK_1 = 4.6$  and  $pK_2 = 6.2$  ( $pI = 5.4$ ). The ampholyte was titrated in the pH 4–7 interval. (B) Computer simulation obtained by assuming  $pK_1 = 4.6$  and  $pK_2 = 9.3$  ( $pI = 6.95$ ). The ampholyte was titrated in the pH 4–10 interval. Note the sharp sigmoidal transition in the pI region in B, suggesting total lack of buffering power (P Wenger and PG Righetti, unpublished).

that at the theoretical pI value the ampholyte does not have any appreciable buffering power and that it is fully ionized. In addition, it is not only isoelectric at pH 6.95, but indeed almost at any pH in the interval 5–9, as seen by the abrupt sigmoidal shape in the pI environment. This species will be a ‘bad’ CA, useless for a well-behaved IEF fractionation.

An important prerequisite for a good CA is that it has a high conductivity at its pI. Regions of low conductivity will absorb much of the applied voltage, thus reducing the field strength and hence the potential resolution in other parts of the gradient. It has been demonstrated that good conductivity is associated with small values of  $pI - pK$ . This is also true for the buffering capacity of an ampholyte. Thus, the parameter  $pI - pK$  (equivalent to  $\frac{1}{2}\Delta pK$ ) becomes the most important factor in selecting CAs exhibiting both good conductivity and buffering capacity ( $\beta$ ).

### Methodology

The structure of CAs (trade names Ampholine, Pharmalyte, Servalyte, and Biolyte, to name but a few) and their general properties are illustrated in **Figure 2**. CAs are oligoprotic amino carboxylic acids, each containing at least four weak protolytic groups, at least one being a carboxyl group and at least one a basic nitrogen atom, but no peptide bonds. In a typical synthesis, a mixture of oligoamines (four to six nitrogens in length, linear and branched) is reacted

**Figure 2** Composition of Ampholine. On the upper left side a representative chemical formula is shown (aliphatic oligoamino oligocarboxylic acids). On the lower left side, portions of hypothetical titration curves of carrier ampholytes are depicted. Right: different pH cuts for wide and narrow range ampholytes.

with an  $\alpha,\beta$ -unsaturated acid (typically acrylic or itaconic acid), at a nitrogen:carboxyl ratio of 2:1.

The dynamics of IEF are illustrated in the simulations of Figure 3. This simulator is quite realistic, since it accepts 150 components and voltage gradients ( $300 \text{ V cm}^{-1}$ ) employed in laboratory practice. Before passage of the current, the column is at constant pH and the multitude of amphoteric buffers is randomly distributed, resulting in reciprocal neutralization. However, each individual CA species will have its own titration curve (see Figure 2, lower left

side) defining different mobilities in the electric circuit. After starting the experiment, the focusing process appears to proceed in two phases, a relative fast separation phase followed by a slow stabilizing phase during which a steady state should be reached. As shown in the bottom tracing, a pH 3–10 gradient appears to be fully established within 10–12 min, with the CAs forming Gaussian-like, overlapping zones of high concentration ( $>100$ -fold increase compared to the initial stage) with the three samples (dyes with pIs of 6.6, 7.4, and 8.6) well focused too.

**Figure 3** Computer-simulated distributions of 140 carrier ampholytes and of three dyes after 12, 100, 500, 1000, 2000, and 5000 min of current flow. The numbers refer to the pI values of the dyes and the arrowheads point to their locations. Successive graphs are presented with a y-axis offset of  $30 \text{ mmol l}^{-1}$ . The arrows at the bottom graph mark the two transient concentration valleys that are characteristic for the stabilizing phase. The cathode is to the right. (Reproduced with permission from Mosher RA and Thormann W (2002) High-resolution computer simulation of the dynamics of isoelectric focusing using carrier ampholytes: The postseparation stabilizing phase revisited. *Electrophoresis* 23: 1803–1814.)

Close to the column ends, large changes of carrier concentrations (valleys) are marked with arrows. This initial distribution of CAs generates an almost linear pH profile. This simulation, however, shows also the major drawback of all CA-based focusing processes: steady state can never be achieved. The two valleys at the extremes migrate inwards, flattening the focused CA from Gaussian into square-shaped peaks, and displacing them toward the terminal electrodes (see the simulated profiles from 100 min to 5000 min). As a result, the pH gradient keeps changing slopes, till it assumes a sigmoidal profile, with marked flattening of the central region with inflection point around neutrality (called plateau phenomenon). This results in a continuous shift of the foci of the focused samples along the column length (see the diverging positions of the three dyes from bottom to top in **Figure 3**).

By and large, most analytical IEF runs are performed in horizontal chambers: the polyacrylamide gel slab rests on a cooling block (in general made of glass or coated aluminum or even beryllium oxide, used as the heat shield of the space shuttle). This horizontal configuration allows one to dispose of electrode reservoirs and of all the hydraulic problems connected with vertical chambers (tight seals, etc.): in fact, anolyte and catholyte are soaked in filter paper strips resting directly on the open gel surface. In addition, most modern chambers contain a cover lid with movable electrodes, which can be adjusted to any gel length (in general from 10 to 25 cm electrode distances). Since thick gels (e.g., 2 mm thick) generate thermal gradients through the gel thickness, resulting in skewed zones (essentially all horizontal chambers have cooling only on one gel face) ultrathin gels (0.2–0.5 mm thin) supported onto a reactive polyester foil (Gel Bond PAG) are today preferred.

## Immobilized pH Gradients

IPGs are based on the principle that the pH gradient, which exists prior to the IEF run itself, is copolymerized, and thus insolubilized, within the polyacrylamide matrix. This is achieved by using, as buffers, a set of up to 10 nonamphoteric, weak acids and bases, called Immobilines, having the following general chemical composition:  $\text{CH}_2=\text{CH}-\text{CO}-\text{NH}-\text{R}$ , where R denotes either three different weak carboxyls, with pKs 3.1, 3.6, and 4.6 (**Table 1**), or five tertiary amino groups, with pKs 6.2, 7.0, 8.5, 9.3, and 10.3 (**Table 2**). This set of eight weak buffers is complemented by one strong acid (pK  $\sim 1$ , 2-acrylamido-2-methyl propane sulfonic acid) and a strong base (pK  $> 12$ , quaternary amino ethyl acrylamide), used only as titrants. During gel polymerization, these buffering species are incorporated into the gel (84–86% conversion efficiency at 50°C for 1 h), by the same free radical reaction used to activate the acrylamide double bond. **Figure 4** depicts a segment of a hypothetical structure of an Immobililine matrix and the process of focusing two proteins in it. It is seen that only the proteins migrate to their steady-state position, whereas the Immobilines remain affixed at their original grafting position in the gel, where a fixed ratio buffering/titrant ions defines the pH locally. This means that, unlike conventional CA-IEF, the pH gradient is stable indefinitely (but it has to pre-exist before the onset of polymerization) and can only be destroyed if and when the polyacrylamide gel is hydrolyzed. Given the sparse distribution of Immobilines in the gel, they behave as isolated charges, able to effectively contribute to the ionic strength of the medium. In conventional IEF, on the contrary, at steady state the ionic strength is exceedingly low ( $< 1$  mequiv.  $\text{l}^{-1}$ ) since the focused carrier ampholytes

**Figure 4** Hypothetical structure of an Immobiline gel and mechanism of the focusing process. The acrylamido acid and basic groups are shown grafted onto the polyacrylamide matrix. Two proteins are shown migrating in the gel at the times  $t=0$ , at  $t=1$  and finally at the steady state, where they reach their respective  $pI$  values ( $pI_1$  and  $pI_2$ ) as points of zero net charge.

form an inner salt and this often results in protein precipitation and smears both at the  $pI$  and in its proximity. In IPGs, the high ionic strength existing in the matrix (typically 10 mequiv.  $l^{-1}$ ) induces protein solubilization at the  $pI$  value (thus CA-IEF is similar to a 'salting-out' milieu and IPGs to a 'salting-in' environment).

Immobiline-based pH gradients can be cast in the same way as conventional polyacrylamide gradient gels, by using a density gradient to stabilize the Immobiline concentration gradient, with the aid of a standard, two-vessel gradient mixer. As shown in the above formula, these buffers are no longer amphoteric, as in conventional IEF, but are bifunctional: at

one end of the molecule the buffering group is located, and at the other end is the acrylic double bond, which will disappear during the grafting process. The three carboxyl Immobilines have rather small temperature coefficients of ionization ( $\text{dpK/dT}$ ) in the 10–25°C range, due to their small standard heats of ionization ( $\sim 1 \text{ kcal mol}^{-1}$ ) and thus exhibit negligible  $\text{pK}$  variations in this temperature interval. On the other hand, the four basic Immobilines exhibit rather large  $\Delta\text{pK}$ s in the same temperature range (as much as  $\Delta\text{pK} = 0.44$  for the  $\text{pK}$  8.5 species) due to their larger heats of ionization ( $6\text{--}12 \text{ kcal mol}^{-1}$ ). Therefore, for reproducible runs and pH gradient calculations, all the experimental parameters have been fixed at 10°C. Temperature is not the only variable that will affect Immobililine  $\text{pK}$ s (and therefore the actual pH gradient generated): additives in the gel that will change the water structure (chaotropic agents, such as urea) or will lower its dielectric constant, and the ionic strength of the solution itself will alter  $\text{pK}$  values.

### Narrow and Ultranarrow pH Gradients

We define the gradients (in the gel slab) from 0.1 to 1 pH unit as ultranarrow and narrow gradients, respectively. Within these limits, in general, one can work on a 'tandem' principle, i.e., one chooses a 'buffering' Immobililine (e.g., a base or an acid), having its  $\text{pK}$  within the desired pH interval, and a 'nonbuffering' Immobililine (e.g., an acid or a base, respectively), having its  $\text{pK}$  at least 2 pH units removed from either  $\text{pH}_{\min}$  or  $\text{pH}_{\max}$  of the pH range. The latter will thus provide equivalents of acid or base, respectively, to titrate the buffering group but will not itself buffer in the desired pH interval. For these calculations, one can resort to modified Henderson–Hasselbalch equations and to rather complex nomograms or simply adopt tabulated recipes, 1 pH unit wide, which start with the pH 3.8–4.8 interval and end with the pH 9.5–10.5 span, separated by 0.1 pH unit increments (58 such recipes have been tabulated). If a narrower pH gradient is needed, this can be derived from any of the 58 pH intervals tabulated by a simple linear interpolation of intermediate Immobililine molarities.

### Extended pH Gradients

For wider pH intervals, one has to mix several buffering species and the situation becomes considerably more complex. This has been solved with the aid of computer programs designed specifically for this purpose. The basic findings are: (1) for generating a linear pH gradient the buffering power has to be

constant throughout the desired pH interval (this is best achieved when the  $\text{pK}$  values are spaced at 1 pH unit interval); (2) to avoid deviations from linearity, the titrants should have  $\text{pK}$ s well outside  $\text{pH}_{\min}$  and  $\text{pH}_{\max}$  of the wanted pH range (in general, at least 2 pH units removed from the limits of the pH interval). As a consequence of this, for pH ranges wider than 4 pH units, two additional Immobilines are needed as titrants: one strongly acidic ( $\text{pK} < 1$ ) and one strongly basic ( $\text{pK} > 12$ ). There are two ways for generating extended pH intervals. In one approach, the concentration of each buffer is kept constant throughout the span of the pH gradient and 'holes' of buffering power are filled by increasing the amounts of the buffering species bordering the largest  $\Delta\text{pK}$ s; in the other approach (varying buffer concentration), the variation in concentration of the various buffers along the width of the desired pH gradient results in a shift of their apparent  $\text{pK}$ s with a concomitant evening-out of the  $\Delta\text{pK}$  values. With the available recipes, preparation of any Immobililine gel is now a trouble-free operation, as all the complex computing routines have been already performed and no further calculations of any type are required.

### Nonlinear, Extended pH Gradients

IPG formulations have been given only in terms of rigorously linear pH gradients. While this has been the only solution adopted so far, it might not be the optimal one in some cases. Altering the pH slope in some portions of the gradient might be required in those pH regions overcrowded with proteins. The reasons for resorting to nonlinear pH gradients are given in the histogram of Figure 5. With the relative abundance of different species, it is clear that an optimally resolving pH gradient should have a gentler slope in the acidic portion, and a steeper course in the alkaline region. Such a general course has been calculated by assigning to each 0.5 pH unit interval in the pH 3.5–10 region a slope inversely proportional to the relative abundance of proteins in that interval; by such a procedure, the ideal (dotted) curve in Figure 5 was obtained. What is also important here is the establishment of a new principle in IPG technology, namely that the pH and density gradients stabilizing it need not be colinear, the possibility existing of modulating the former, by locally flattening of pH gradients for increased resolution, while leaving unaltered the latter. Though we have given here only one example of a nonlinear extended pH gradient, clearly the possibility exists of modulating in the same fashion any narrower pH interval.

### Examples on the Resolving Power

What can IPGs achieve in practice? One interesting example is given in **Figure 6**: here a preparation of bovine tubulin is resolved into at least 21 isoforms, in the IPG pH 4–7 interval. The advantage of the IPG technique is that, unlike in CA-IEF, true steady-state patterns are obtained, rendering the method highly reproducible. The very low conductivity of the IPG strips, in addition, allows much higher voltage

gradients to be delivered along the focusing axis, thus producing much sharper protein zones and ultimately leading to much higher resolution (it is recalled here that the resolving power of CA-IEF is  $\sim 0.01$  pH units, whereas that of IPG is greater by one order of magnitude, i.e., 0.001 pH units).

### Capillary Isoelectric Focusing

Although capillary isoelectric focusing (cIEF) still is beleaguered by some problems (notably how to cohabit with the ever present hazard of electroosmotic flow, EOF), the technique is gaining momentum and is becoming quite popular, especially in the analysis of r-DNA products and of heterogeneity due to differential glycosylation patterns and to 'protein aging,' i.e., asparagine (Asn) and glutamine (Gln) deamidation *in vitro*. A spin-off of cIEF is zone electrophoresis in zwitterionic, isoelectric buffers, a technique that exploits all the basic concepts of IEF and offers unrivalled resolution due to fast analysis in high-voltage gradients. Capillary electrophoresis offers some unique advantages over conventional gel slab techniques: the amount of sample required is truly minute (a few microliters at the injection port, but only a few nanoliters in the moving zone); the analysis time is, in general, very short (often just a few minutes) due to the very high voltages applicable; analyte detection is online and is coupled to a fully instrumental approach (with

**Figure 6** IEF of 25 µg bovine tubulin in an IPG pH 4–7 gradient. Bottom: the entire IPG strip; middle: enlarged detail of the principal protein-containing region; top: scan of this region. At least 21 bands are visible. Zones in which  $\alpha$ - and  $\beta$ -tubulin are known to focus are indicated. The 11 cm long IPG strip was rehydrated for 14 h at 22°C. Focusing was for 1 h at 500 V, 1 h at 1000 V, and 3 h at 5000 V, all at 20°C. Current was limited to 50 µA per strip. The positions of positive and negative electrodes are indicated. automatic storage of electropherograms on a magnetic support).

A principal difference between IEF in a gel and in a capillary is that, in the latter, mobilization of the focused proteins past the detector has to be carried out if an online imaging detection system is not being used. Mainly three techniques are used: chemical and hydrodynamic flow mobilization (in coated capillaries) and mobilization utilizing the EOF (in uncoated or partially coated capillaries). The last approach is troublesome, though, since the transit times of the focused zones change severely from run to run; thus, it is preferable to perform cIEF in well-coated capillaries, where EOF is completely suppressed.

Basically, most of the rules that apply to CA-IEF in gel slabs are also valid in cIEF. It should be noted, though, that direct measurements of pH gradients cannot be performed in cIEF; thus, one has to resort to the use of pI markers. Of particular interest is a set of 16 synthetic peptides, engineered so as to cover the pH 3.5–10 interval; they have the advantage, over protein pI markers, of being stable and not generating spurious peaks due to 'aging,' as typical of macromolecules. In addition to conventional cIEF in standard capillaries (typically with a lumen of 50–100  $\mu\text{m}$  and with lengths of 25–50 cm) the recent trend is to adopt miniaturized chambers microfabricated in plastic microfluidic devices, such as polymethylmethacrylate, poly(ethylene terephthalate), and polycarbonate. In such devices, the separation channel can be just a few centimeters long; longer channels (e.g., 16 cm long) have to be machined in a serpentine fashion. Finally, cIEF is used increasingly as the first dimension of 2D maps, by which the eluate from the capillary separation is interfaced with mass spectrometry, for mass separation and characterization. The final result is a true 2D map, having pI/ $M_r$  coordinates, just like in gel-based techniques. It has been claimed that cIEF displays a peak capacity of  $\sim 800$  and sample concentration factors of  $\sim 500$ -fold, with a resolving power approaching  $\Delta(\text{pI})$  of  $\sim 0.005$ .

Some examples of separations that can be obtained by cIEF are shown in Figure 7. For species with minute  $\Delta\text{pIs}$ , one can resort to nonlinear pH gradients, by addition of zwitterions that alter the pH locally. In Figure 7A, one can appreciate an outstanding separation of fetal (F), adult (A), and acetylated fetal (Fac) hemoglobins. Another difficult separation, between adult and glycated hemoglobins, is shown in Figure 7B. Both separations are of interest in clinical chemistry: in the first case, for screening of thalassemias in umbilical cord blood, in the second instance for screening for diabetic patients.

**Figure 7** cIEF of hemoglobins. (A) separation of Hb F, A, and  $\text{F}_{\text{ac}}$ . Background electrolyte: 5% Ampholine, pH 6–8, added with 3% short-chain polyacrylamide and  $100 \text{ mmol l}^{-1}$   $\beta$ -Ala. (B) separation of an artificial mixture of 65% HbA and 35% Hb A1c in 5% Ampholine, pH 6–8, added with an equimolar mixture of separators,  $0.33 \text{ mol l}^{-1}$   $\beta$ -Ala and  $0.33 \text{ mol l}^{-1}$  6-amino caprioc acid. Anolyte:  $20 \text{ mmol l}^{-1}$   $\text{H}_3\text{PO}_4$ ; catholyte:  $40 \text{ mmol l}^{-1}$  NaOH. Sample loading: by pressure, for 60 s. Focusing run: 20 kV constant at  $7 \mu\text{A}$  (initial) to  $1 \mu\text{A}$  (final current),  $20^\circ\text{C}$  in a Bio Rad Bio Focus 2000 unit. Capillary: coated with poly(*N*-acryloyl amino ethoxy ethanol),  $25 \mu\text{m}$  ID, 23.6/19.1 total/effective length. Mobilization conditions: with  $200 \text{ mmol l}^{-1}$  NaCl added to anolyte, 22 kV. Detection at 415 nm.

As a corollary of focusing techniques, one should mention capillary zone electrophoresis in isoelectric buffers. This is an interesting development of cIEF, whereby zone electrophoresis can be performed in

**Figure 8** Representative CZE run of gliadins, obtained by sequential extraction of flour, from four different cultivars of durum (panel A) and of soft (panel B) wheat. Runs performed in  $40 \text{ mmol l}^{-1}$  Asp buffer, added with  $7 \text{ mol l}^{-1}$  urea and 0.5% HEC (apparent pH: 3.9). Conditions:  $50 \mu\text{m}$  ID, 30 cm long capillary, run at  $1000 \text{ V cm}^{-1}$  at room temperature. Detection at 214 nm (from Capelli *et al.*, 1998).

isoelectric, very-low-conductivity buffers, allowing the highest possible voltage gradients and thus much improved resolution of peptides and proteins due to reduced diffusion in short analysis times. Although originally described in alkaline pH values (notably in lysine,  $\text{pI}=9.87$ ) and at neutral pH (notably histidine buffers,  $\text{pH}=\text{pI}=7.6$ , albeit mostly for DNA and oligonucleotides), it has been found that acidic zwitterions offer an extra bonus: they allow the use of uncoated capillaries, due to protonation of silanols at the prevailing pH of the background electrolyte. A number of such acidic, isoelectric buffers have been described: cysteic acid ( $\text{pI}=1.80$ ); iminodiacetic acid ( $\text{pI}=2.23$ ); aspartic acid (Asp,  $\text{pI}=2.77$ ), and glutamic acid (Glu,  $\text{pI}=3.22$ ). **Figure 8** gives an example of such separations, performed in  $50 \text{ mmol l}^{-1}$  Asp, for the screening of gliadins in extracts from durum and soft wheat. Voltages as high as  $1000 \text{ V cm}^{-1}$  can be applied, with analysis times of only a few minutes, in 30-cm long capillaries.

viscosity (although viscosity is generally higher than for traditional organic solvents).

### Introduction

Ionic liquids are solvents comprised entirely of ions. This includes materials also known as molten salts, fused salts, liquid organic salts, nonaqueous ionic liquids, and room-temperature ionic liquids, but excludes aqueous and nonaqueous solutions of salts. Ionic liquids are inorganic or organic salts and their mixtures at a temperature above their melting point where they form stable liquids with favorable solvent properties. Roughly, half of all common inorganic salts have melting points below 500°C and many of these form eutectic mixtures with even lower melting points. Most organic salts have melting points below 400°C. Many of these, however, decompose at temperatures close to their melting points. An exception is the large number of alkylammonium, alkylphosphonium, imidazolium, and other heterocyclic cations with anions of low nucleophilicity (e.g., sulfonate, tetrafluoroborate, hexafluorophosphate, and bis(trifluoromethylsulfonyl)amide). These salts possess stable liquid ranges that are often thermally stable at temperatures more than 100°C above their melting point. A subset of these salts, known as room-temperature ionic liquids, has melting points below room temperature and is particularly promising for chromatographic and electrophoretic applications. At present, over 200 room-temperature ionic liquids are known, but only a few are fully characterized, explained by the fact that most were identified during the 1990s. Favorable properties include: virtually no vapor pressure; low flammability; high solubility for organic and inorganic compounds; high conductivity and a large window for electrochemical reactions; good thermal stability; and relatively low

### Inorganic Salts

Electrophoresis in fused inorganic salts and their eutectic mixtures were developed in the 1960s for the separation of inorganic ions and isotopes. Later, electrophoresis in ionic liquids was used for fundamental studies of ion solvation, to gain insight into the mechanism of ion transport, and to study complexation equilibria in the absence of competition from water molecules. As a separation method, it is virtually unused today, as more convenient techniques for separating ions, including isotopes, are now available. As a tool to probe the fundamental physical properties of ionic liquids, it finds occasional use. Electrophoresis in inorganic ionic liquids requires a special apparatus that can tolerate the high temperatures and corrosive nature of the fused salts and their electrolysis products.

A suitable support for electrophoresis should exhibit the following properties: (1) have good thermal stability to allow its use at high temperatures; (2) be chemically inert to allow its use with corrosive ionic liquids; (3) be a poor electrical conductor; (4) have a low obstruction factor; and (5) should not compete with electrophoretic separations by adsorbing sample ions. For flatbed separations glass fiber or asbestos paper strips are generally used. Powdered thin layers made by spraying aqueous suspensions of ceramic oxides onto sintered ceramic strips can be used as well. The support is first homogeneously impregnated with the ionic liquid. Then a small amount of the sample is spotted on the support (usually at the center). Separations are then carried out as in normal flatbed electrophoresis, except that here evaporation of the ionic liquid is negligible and high temperatures

### Introduction

Ionic liquids are solvents comprised entirely of ions. This includes materials also known as molten salts, fused salts, liquid organic salts, nonaqueous ionic liquids, and room-temperature ionic liquids, but excludes aqueous and nonaqueous solutions of salts. Ionic liquids are inorganic or organic salts and their mixtures at a temperature above their melting point where they form stable liquids with favorable solvent properties. Roughly, half of all common inorganic salts have melting points below 500°C and many of these form eutectic mixtures with even lower melting points. Most organic salts have melting points below 400°C. Many of these, however, decompose at temperatures close to their melting points. An exception is the large number of alkylammonium, alkylphosphonium, imidazolium, and other heterocyclic cations with anions of low nucleophilicity (e.g., sulfonate, tetrafluoroborate, hexafluorophosphate, and bis(trifluoromethylsulfonyl)amide). These salts possess stable liquid ranges that are often thermally stable at temperatures more than 100°C above their melting point. A subset of these salts, known as room-temperature ionic liquids, has melting points below room temperature and is particularly promising for chromatographic and electrophoretic applications. At present, over 200 room-temperature ionic liquids are known, but only a few are fully characterized, explained by the fact that most were identified during the 1990s. Favorable properties include: virtually no vapor pressure; low flammability; high solubility for organic and inorganic compounds; high conductivity and a large window for electrochemical reactions; good thermal stability; and relatively low

### Inorganic Salts

Electrophoresis in fused inorganic salts and their eutectic mixtures were developed in the 1960s for the separation of inorganic ions and isotopes. Later, electrophoresis in ionic liquids was used for fundamental studies of ion solvation, to gain insight into the mechanism of ion transport, and to study complexation equilibria in the absence of competition from water molecules. As a separation method, it is virtually unused today, as more convenient techniques for separating ions, including isotopes, are now available. As a tool to probe the fundamental physical properties of ionic liquids, it finds occasional use. Electrophoresis in inorganic ionic liquids requires a special apparatus that can tolerate the high temperatures and corrosive nature of the fused salts and their electrolysis products.

A suitable support for electrophoresis should exhibit the following properties: (1) have good thermal stability to allow its use at high temperatures; (2) be chemically inert to allow its use with corrosive ionic liquids; (3) be a poor electrical conductor; (4) have a low obstruction factor; and (5) should not compete with electrophoretic separations by adsorbing sample ions. For flatbed separations glass fiber or asbestos paper strips are generally used. Powdered thin layers made by spraying aqueous suspensions of ceramic oxides onto sintered ceramic strips can be used as well. The support is first homogeneously impregnated with the ionic liquid. Then a small amount of the sample is spotted on the support (usually at the center). Separations are then carried out as in normal flatbed electrophoresis, except that here evaporation of the ionic liquid is negligible and high temperatures

are necessary to maintain the electrolyte (fused salt) in the liquid state.

Figure 1 shows a typical apparatus for flatbed electrophoresis. It is fabricated from glass or fused silica. An electric field is applied to the impregnated support by two electrodes immersed in separate reservoirs at either end of the support. The choice of

**Figure 1** Apparatus for zone electrophoresis in inorganic ionic liquids. the electrodes depends exclusively upon their resistance to corrosion under the experimental conditions. The anode is generally platinum, and other materials such as tungsten, nickel, copper, or graphite are used as the cathode. Platinum may be attacked by the alkali metals formed at the cathode during electrophoresis. This kind of apparatus is best housed in an oven, as shown in Figure 2. Provision is also made to circulate a gas to remove volatile electrolysis products such as chlorine. At the end of the experiment, the substance is located by usual spot test reactions.

The technique is fairly rapid and simple; but when accurate data are required, several precautions are necessary. Auxiliary electrodes (A and A' in Figure 1) are required for an accurate measurement of the applied field due to polarization of the working electrodes. Temperature gradients (external or Joule heating) are minimized by choice of the operating conditions. The reservoirs have to be leveled to avoid flow of ionic liquid by siphon effects. Relatively low temperatures, i.e., between 150°C and 300°C, are commonly used. Suitable eutectic mixtures include lithium nitrate–potassium nitrate (43:57) at 160°C, sodium nitrate–potassium nitrate (50:50) at 250°C, and lithium chlorate–potassium chlorate (76:24) at 300°C. Potassium or sodium nitrates can be used at 350°C. Additives can be added to prevent precipitation of metal oxides and complexing agents to adjust selectivity. Some representative separations of metal ions on glass fiber paper are shown in Figure 3.

Column electrophoresis is carried out in an apparatus such as that shown in Figure 4. Glass powder, alumina, splinters, or quartz powder is used as a support. The support is first impregnated with the ionic liquid, then a solution of the sample is applied at the center of the separation column and the electric field applied. Column electrophoresis is commonly used for isotope separations.

The relative mass difference of isotopes in ionic liquids is higher than in aqueous solution. This is because solvation of ions by water tends to diminish mass differences. Consequently, greater differences in electrophoretic mobility are possible in ionic liquids. Countercurrent electrophoresis in columns allowed isolation of highly enriched isotope mixtures without great difficulty. Some examples of the mass difference effect are summarized in **Table 1**. These results depend on the temperature as well as the composition of the ionic liquid.

## Organic Salts

Some typical room temperature ionic liquids and their physical properties are summarized in **Table 2**. The viscosity of most ionic liquids is substantially greater than traditional solvents. Elevated temperatures or dilution with conventional solvents of high dielectric constant can be used to lower the viscosity into a more desirable range. High viscosity, variable purity, and interference in absorbance detection at low wavelengths are the primary problems for the wider use of ionic liquids in electrophoresis at present. On the other hand, new ionic liquids are introduced at frequent intervals, and knowledge is

building on the design of ionic liquids for specific applications, which might address these problems at a future date.

Ionic liquids have been used as background electrolytes in aqueous and nonaqueous capillary

electrophoresis. The miscibility of the ionic liquids with water and organic solvents is determined by the structure of the salt. While some are immiscible with water, most are miscible with polar organic solvents. Bulky organic groups incorporated in either the cation or anion tend to diminish solubility in water. The most common co-solvents for capillary electrophoresis are water, acetonitrile, and mixtures of acetonitrile and methanol. In solvents of low polarity, a lack of free ions diminishes the effectiveness of ionic liquids for electrophoresis. 1,3-Dialkylimidazolium-based ionic liquids are adsorbed onto the capillary wall from aqueous solution. In so doing they reverse the direction of electroosmotic flow, more or less independent of pH. A number of different sample types (DNA fragments, metal ions, ionic dyes, poly(phenols), etc.) were separated using 1,3-dialkylimidazolium-based ionic liquids as a major component of the electrolyte solution without significant operational difficulties. The separation of poly(phenols) is shown in Figure 5. A contributing factor to this separation is the association of the poly(phenols) with the 1,3-dialkylimidazolium cations coating the capillary wall and/or as components of the electrolyte solution.

### Introduction

Zone electrophoresis became extremely popular in the early 1960s, with the introduction of polyacrylamide matrices and the discovery of the concept of discontinuous buffers. We will first review the chemistry of acrylamide monomers and cross-linkers and then discuss the following: disk electrophoresis, pore gradient electrophoresis, and sodium dodecyl sulfate electrophoresis. While these techniques are typically applied to protein analysis, there are at least two important fields of application of polyacrylamide gels to nucleic acid analysis: DNA-sequencing gels and temperature gradient gels. We will conclude with the most recent trend, especially in capillary zone electrophoresis, the use of ‘physical’ (i.e., uncross-linked) versus ‘chemical’ (i.e., cross-linked) gels. Polyacrylamide gel electrophoresis is routinely abbreviated as PAGE.

### On the Chemistry of Polyacrylamides

The popularity of polyacrylamide gels stems from several fundamental properties: (1) optical clarity, including ultraviolet (UV) (280 nm) transparency (but it absorbs strongly at 210 nm, a region of good response of the peptide bond; thus, its use is not recommended as sieving polymer in capillary electrophoresis of proteins and peptides at this wavelength, where UV-transparent polymers, such as celluloses, should be preferred); (2) electrical neutrality, due to the absence of charged groups; and (3) availability in a wide range of pore sizes. Their chemical formula, as commonly polymerized from acrylamide and *N,N'*-methylene bisacrylamide (Bis), is shown in **Figure 1**, together with that of two most widely employed catalysts, peroxydisulfate (ammonium or potassium) and *N,N,N',N'*-tetramethylethylenediamine. Normal polyacrylamide gels (i.e., cross-linked with

standard amounts of Bis, 3–5%) have porosities that decrease linearly with the total amount of monomers (%T: total monomer concentration per 100 ml of solution) in them and which are substantially smaller than the corresponding agarose gels. However, highly cross-linked gels (>10%C) (%C: grams of cross-linker per 100 g of total monomers) can, at very high cross-link levels (>30%C), have porosities comparable with, or even greater than, agarose matrices. High %C polyacrylamide matrices, however, are brittle, opaque, and tend to collapse and exude water above 30%C. Thus, their use is at present limited.

Hydrophilic gels are considered to be a network of flexible polymer chains, into whose interstices macromolecules are forced to migrate by an applied potential difference, according to a partition governed by steric factors. Large molecules can only penetrate into regions where the meshes in the net are large, while small molecules find their way into tightly knit regions of the network, even close to the cross-links. Different models of the gel structure have been described: geometric, statistical, and thermodynamic. Perhaps the best way to envision a hydrophilic matrix is to consider it as being composed of two interlacing fluid compartments endowed with different frictional coefficients. No matter how we describe the gel structure, it should be remembered that, in general, agaroses are more porous than polyacrylamides and that these two matrices are used complementary to each other. A number of new monomers and cross-linkers, with unique properties, have been synthesized over the years. They are listed in **Tables 1** and **2**, respectively, and will be described below.

### Trisacryl Gels

These gels are derived from the polymerization of the monomer *N*-acryloyl-2-amino-2-hydroxymethyl-1,3-propanediol. The trisacryl monomer creates a microenvironment that favors the approach of hydrophilic solutes (proteins) to the gel polymer surface, since the polyethylene backbone is buried underneath a layer

### Introduction

Zone electrophoresis became extremely popular in the early 1960s, with the introduction of polyacrylamide matrices and the discovery of the concept of discontinuous buffers. We will first review the chemistry of acrylamide monomers and cross-linkers and then discuss the following: disk electrophoresis, pore gradient electrophoresis, and sodium dodecyl sulfate electrophoresis. While these techniques are typically applied to protein analysis, there are at least two important fields of application of polyacrylamide gels to nucleic acid analysis: DNA-sequencing gels and temperature gradient gels. We will conclude with the most recent trend, especially in capillary zone electrophoresis, the use of ‘physical’ (i.e., uncross-linked) versus ‘chemical’ (i.e., cross-linked) gels. Polyacrylamide gel electrophoresis is routinely abbreviated as PAGE.

### On the Chemistry of Polyacrylamides

The popularity of polyacrylamide gels stems from several fundamental properties: (1) optical clarity, including ultraviolet (UV) (280 nm) transparency (but it absorbs strongly at 210 nm, a region of good response of the peptide bond; thus, its use is not recommended as sieving polymer in capillary electrophoresis of proteins and peptides at this wavelength, where UV-transparent polymers, such as celluloses, should be preferred); (2) electrical neutrality, due to the absence of charged groups; and (3) availability in a wide range of pore sizes. Their chemical formula, as commonly polymerized from acrylamide and *N,N'*-methylene bisacrylamide (Bis), is shown in **Figure 1**, together with that of two most widely employed catalysts, peroxydisulfate (ammonium or potassium) and *N,N,N',N'*-tetramethylethylenediamine. Normal polyacrylamide gels (i.e., cross-linked with

standard amounts of Bis, 3–5%) have porosities that decrease linearly with the total amount of monomers (%T: total monomer concentration per 100 ml of solution) in them and which are substantially smaller than the corresponding agarose gels. However, highly cross-linked gels (>10%C) (%C: grams of cross-linker per 100 g of total monomers) can, at very high cross-link levels (>30%C), have porosities comparable with, or even greater than, agarose matrices. High %C polyacrylamide matrices, however, are brittle, opaque, and tend to collapse and exude water above 30%C. Thus, their use is at present limited.

Hydrophilic gels are considered to be a network of flexible polymer chains, into whose interstices macromolecules are forced to migrate by an applied potential difference, according to a partition governed by steric factors. Large molecules can only penetrate into regions where the meshes in the net are large, while small molecules find their way into tightly knit regions of the network, even close to the cross-links. Different models of the gel structure have been described: geometric, statistical, and thermodynamic. Perhaps the best way to envision a hydrophilic matrix is to consider it as being composed of two interlacing fluid compartments endowed with different frictional coefficients. No matter how we describe the gel structure, it should be remembered that, in general, agaroses are more porous than polyacrylamides and that these two matrices are used complementary to each other. A number of new monomers and cross-linkers, with unique properties, have been synthesized over the years. They are listed in **Tables 1** and **2**, respectively, and will be described below.

### Trisacryl Gels

These gels are derived from the polymerization of the monomer *N*-acryloyl-2-amino-2-hydroxymethyl-1,3-propanediol. The trisacryl monomer creates a microenvironment that favors the approach of hydrophilic solutes (proteins) to the gel polymer surface, since the polyethylene backbone is buried underneath a layer

**Figure 1** The polymerization reaction of acrylamide. The structure of acrylamide, *N,N'*-methylenebisacrylamide (Bis) and of a representative segment of cross-linked polyacrylamide are shown. Initiators, designated by *i*, shown are peroxodisulfate, riboflavin, and *N,N,N',N'*-tetramethylethylenediamine (TEMED). Light is designated as  $h\nu$ . (Reprinted with permission from Chrambach A and Rodbard D (1971) The polymerization reaction of acrylamide. *Science* 172: 440–451.)

of hydroxymethyl groups. Thus, this type of matrix has an obvious advantage over polyacrylamide supports, which, lacking this protective hydrophilic layer, have a more pronounced hydrophobic character (Trisacryl, with a partition coefficient,  $P$ , of 0.01, is in fact the most hydrophilic monomer ever reported, bearing in mind that even acrylamide, considered to be rather hydrophilic, has a  $P = 0.2$ ). However, this monomer degrades with zero-order kinetics; thus, its use in electrophoresis is quite limited. The reason for this instability is the fact that Trisacryl constantly forms hydrogen bonds between the  $-OH$  groups and the carbonyl of the amido group; this activates a mechanism of 'N–O acyl transfer', which leads to quick hydrolysis of the amido bond even under mild alkaline conditions. The same drawbacks apply to the other very hydrophilic monomer, *N*-acryloyl-1-amino-1-deoxy-D-glucitol, which undergoes autocatalytic hydrolysis at alkaline pH values and is thus just as unstable as Trisacryl.

### ACM-BAP Gels

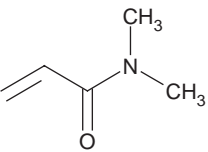

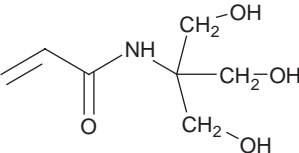

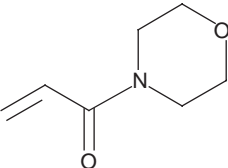

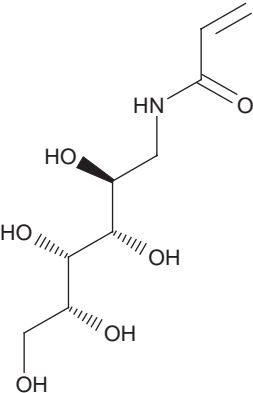

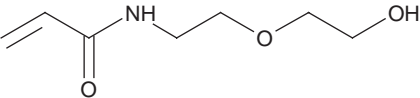

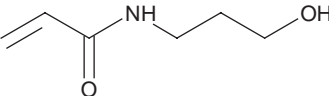

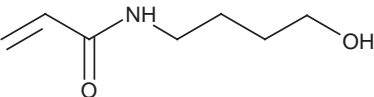

A couple of novel monomers imparting peculiar properties to polyacrylamide-type gels were reported in 1984: acryloyl morpholine (ACM) and bisacrylyl piperazine (BAP, a cross-linker). These gels exhibited some interesting features: due to the presence of the

morpholino ring on the nitrogen involved in the amido bond, the latter was rendered stable against alkaline hydrolysis, which bedevils conventional polyacrylamide matrices. In addition, such matrices are fully compatible with a host of hydro-organic solvents, thus allowing electrophoresis in mixed phases.

### Other Monomers Extremely Resistant to Hydrolysis

At the other extreme of the hydrophilicity scale is located DMA (*N,N'*-dimethylacrylamide): very high hydrophobicity ( $P = 0.5$ ), but extreme resistance to alkaline hydrolysis (approximately three orders of magnitude more stable). *N*-Acryloylaminoethoxyethanol (AAEE) is a novel monomer combining high hydrophilicity with extreme hydrolytic stability. As a free monomer, it has 10 times higher resistance to hydrolysis than plain acrylamide, but as a polymer its stability (in 0.1 M NaOH, 70°C) is 500 times higher. The stratagem: the  $\Omega$ -OH group in the *N*-substituent was removed enough from the amido bond so as to impede formation of hydrogen bonds with the amido carbonyl; if at all, the oxygen in the ethoxy moiety of the *N*-substituent would act as a preferential partner for *H*-bond formation with the  $\Omega$ -OH group. Acryloylaminopropanol (AAP), in which the ether group on the *N*-substituent was removed and the

**Table 1** Structural data on different types of *N*-substituted acrylamide monomers

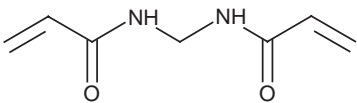

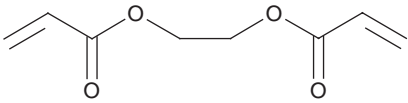

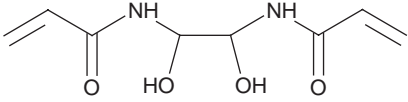

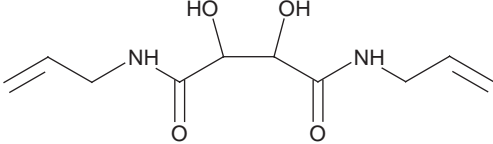

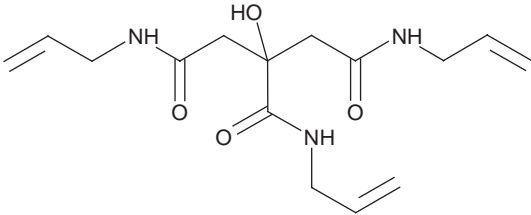

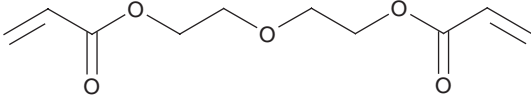

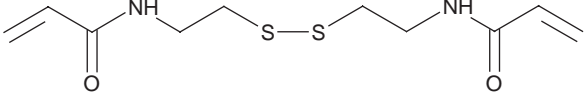

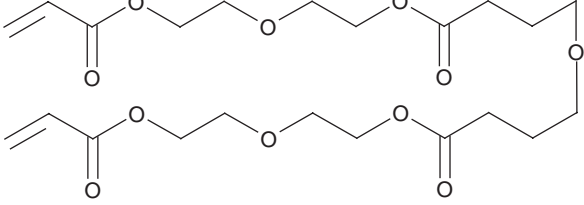

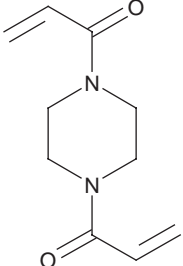

Name	Chemical formula	$M_r$
<i>N,N</i> -Dimethylacrylamide (DMA)		99
<i>N</i> -Acryloyl-2-amino-2-hydroxy methyl-1,3-propane (Trisacryl)		175
<i>N</i> -Acryloylmorpholine		141
<i>N</i> -Acryloyl-1-amino-1-deoxy-D-glucitol		235
<i>N</i> -Acryloylaminoethoxyethanol		159
<i>N</i> -Acryloylaminopropanol		129
<i>N</i> -Acryloylaminobutanol		143

chain shortened, appears to be even more hydrophilic than AAEE ( $P = 0.1$  for AAP versus  $P = 0.13$  for AAEE) and highly resistant to hydrolysis as compared to free acrylamide (hydrolysis constant of AAP  $0.008 \text{ l mol}^{-1} \text{ min}^{-1}$  versus  $0.05 \text{ l mol}^{-1} \text{ min}^{-1}$  for acrylamide, in an alkaline milieu).

#### Different Cross-Linkers

The versatility of polyacrylamide gels is also shown by the large number of cross-linkers, besides Bis, which can be used to cast gels with peculiar properties for different fractionation purposes. They are

**Table 2** Structural data on different types of cross-linkers

Name	Chemical formula	$M_r$	Chain length
<i>N,N'</i> -Methylene bisacrylamide (Bis)		154	9
Ethylene diacrylate (EDA)		170	10
<i>N,N'</i> -(1,2-Dihydroxyethylene) bisacrylamide (DHEBA)		200	10
<i>N,N'</i> -Diallyltartardiamide (DATD)		228	12
<i>N,N',N''</i> -Triallylcitric triamide (TACT)		309	12–13
Poly(ethylene glycol diacrylate) 200 (PEGDA <sub>200</sub> )		214	13
<i>N,N'</i> -Bisacrylyl cystamine (BAC)		260	14
Poly(ethylene glycol diacrylate) 400 (PEGDA <sub>400</sub> )		400	25
<i>N</i> -Bisacrylylpiperazine (BAP)		194	10

listed in Table 2. DHEBA can be used for casting reversible gels, since the 1,2-diol structure of DHEBA renders them susceptible to cleavage by oxidation with periodic acid. The same principle should also apply to DATD gels. Alternatively EDA gels could be used, since this cross-linker contains ester bonds that undergo base-catalyzed hydrolytic cleavage. The poly(ethylene glycol diacrylate) cross-link belongs to the same series of ester derivatives. As the latest addition to the series, BAC gels, which contain a disulfide bridge cleavable by thiols, have been described. These gels appear to be particularly useful for fractionation of RNA, and are the only ones that can be liquefied under mild and almost physiological conditions. Practically any cross-linker can be used, but definitely DATD and TACT should be avoided since, being allyl derivatives, they are inhibitors of gel polymerization when admixed with acrylic double bonds. Their use at high %C is simply disastrous. BAC is extremely hydrophobic, so its use in protein separations should be discouraged.

## Disk Electrophoresis

This method originated in the early 1960s, due to the theoretical and methodological breakthroughs of Ornstein and Davis. Before this time, zone electrophoresis was essentially performed in 'continuous' buffers, having the same composition (in buffering ions and titrants) and same pH along the migration

path and the electrolyte reservoirs. The amazing resolving power of disk electrophoresis is due to four such discontinuities: (1) in the gel matrix; (2) in the pH of the buffers; (3) in the buffer conductivity; and (4) in the types of ions present in the buffers (leading and trailing ions).

The matrix in Figure 2 is divided into three sections (from bottom): a 'separation' or 'running' gel; a 'spacer' or 'stacking' gel; and a sample gel. A few discontinuities exist at the running/stacking interface: the bottom gel is of small pore size, while the second and third layers consist of wider pore structures. Within the running/stacking interface, a pH discontinuity also exists. In fact, the running gel is buffered at pH 8.9, while spacer and sample gels are titrated to pH 6.7. The spacer and sample gel segments are also low-conductivity regions (third discontinuity), which means that a higher voltage gradient will be generated in these zones upon passage of the electric current. Below (i.e., in the running gel) and above (i.e., in the cathodic reservoir) these two gel segments, high-conductivity regions are to be found. A fourth discontinuity exists at the sample gel/upper electrode buffer interface: below it only  $\text{Cl}^-$  (leading) ions are present, above it only glycinate (trailing or terminating) ions are to be found.

This intricate setup has to satisfy an equation derived in 1897 by Kohlrausch (the regulating function), which links the concentration ratio of the fastest (leading, L) and slowest (terminating, T) ions to

**Figure 2** Set-up for disk electrophoresis. (A) Tree-layer polyacrylamide gel ready for the run; (B) isotachophoretic sample component stacking during the first few minutes of run (the process starts in the sample gel and has to be completed when leaving the spacer gel); (C) progress of separation in the running gel (Reproduced from Ornstein L (1964) *Annals New York Academy of Sciences* 121: 321–349).

their respective mobilities:

$$C_L/C_T = [M_L/(M_L + M_R)][(M_T + M_R)/M_T] \quad [1]$$

where  $C$  is the concentration,  $M$  the mobility, and  $R$  denotes the common counterion. If all the ions in the system are arranged in such a way that:  $M_{(\text{leading ion})} > M_{(\text{proteins})} > M_{(\text{trailing ion})}$  (where all the ions have the same charge, i.e., migrate to the same electrode) then, upon applying a voltage gradient, the ions will migrate down the cylinder with equal velocity and the boundary between each adjacent species will be maintained. This process has been called steady-state stacking or isotachopheresis. In more detail, as soon as the circuit is closed,  $\text{Cl}^-$  (fastest moving) ions are swept down the column toward the anode. Just behind this boundary, all protein ions will start arranging themselves in order of their mobilities, the lowest pI component next to the  $\text{Cl}^-$  boundary, the highest pI species coming at the end. This stacking process begins in the sample gel and is terminated in the spacer gel. It is important that these two gels are highly porous, so that protein ions in them move solely according to their charge (mobility), thus satisfying eqn [1], and not as a function of their size. The end of this series is the glycinate ion, which is why sample and spacer gels are buffered at pH 6.7. Gly has a theoretical isoelectric point (pI) = 6.0, but, indeed, as shown by its titration curve, is almost isoelectric even at pH 6.7, so that its anionic mobility is extremely small; in any event smaller than the slowest protein ion. As the isotachopheretic series moves down the sample and spacer gels, the width of the pH 6.7 zone shrinks gradually (see Figure 2) since the pH 8.3 glycinate buffer (catholyte) is drawn into the gel, following the pH 6.7/8.3 boundary.

As the last protein zone enters the running gel, the various protein disks now overrun each other, since they experience a strong frictional force, due to the sieving matrix in the small-pore gel, so that now their velocity is a function of their charge/mass ratio. Only the  $\text{Cl}^-$  is unaffected. In addition, as the zwitterionic glycinate ion enters the pH 8.9 zone, its negative charge density strongly increases, so that it moves ahead and closely follows the  $\text{Cl}^-$  leading ion. As Gly<sup>-</sup> sweeps down the running gel (and increases its concentration in this zone due to its mobility increment) the pH increases from pH 8.9 to 9.5 (the pK of the Gly amino group) so that now the net charge on Gly is  $-0.5$ . As a last consequence of this further pH jump, all proteins experience an additional mobility increment. To summarize these events, in the sample and spacer gels two basic phenomena occur: (1) all protein ions are sorted out and physically separated

according to their pIs; (2) each protein ion is strongly concentrated in extremely thin starting zones (disks of barely a few micrometer thickness; a concentration process of more than 1000-fold).

Besides the obvious applications for the analysis of purity of a protein sample, disk electrophoresis can be used for physicochemical determinations. If the protein under analysis is run in a series of gels of different concentrations (% $T$ ) and the relative mobility ( $R_m$ : defined as the ratio between the distances migrated by a given protein and a tracking dye) in each gel measured, a linear plot of  $\log R_m$  versus % $T$  can be constructed (Ferguson plot). This plot can yield a wealth of information: the slope of this line is a measure of molecular size and is designated as the retardation coefficient ( $K_R$ ). The antilog of the y-intercept of this line ( $Y = R_m$  when  $T = 0$ ) is a measure of the free electrophoretic mobility (i.e., when no gel is present) and therefore of net charge. Since it has been demonstrated that for globular proteins there is a linear relationship between  $\sqrt{K_R}$  and the molecular radius ( $R$ ), the latter can be calculated from  $K_R$  measurements. Once the free mobility ( $m_o$ , calculated from  $Y_o$ ) and  $R_m$  (calculated from  $K_R$ ) are known, one can calculate the net charge on the molecule by using the classical theory of electrophoresis. Moreover, if Ferguson plots are measured for all the proteins in a mixture, the slopes of the different lines will immediately tell if the different components have similar size but different charge, or similar charge but different size, or if they differ in both size and charge. An example of a Ferguson plot is given in Figure 3: when bovine serum albumin (BSA) is run in a series of gels from 4% to 10% $T$ , a family of curves of different slopes is obtained, representing oligomers (from monomer to heptamer) of BSA.

## Electrophoresis in Porosity Gradients

Running macromolecules not in a gel of uniform concentration, but in a continuously varying matrix concentration (which results in a porosity gradient), has the effect of compacting the protein zones along the running track, as the band front is, at any given time, at a gel concentration somewhat higher than the rear of the band, so that the former is decelerated continuously. A progressive band sharpening thus results. There are other reasons for resorting to gels of graded porosity. Disk electrophoresis separates macromolecules on the basis of both size and charge differences. If the influence of molecular charge could be eliminated, then clearly the method could be used with a suitable calibration for measuring molecular size ( $M_r$ ). This has been accomplished with two main

**Figure 3** Plot of the logarithm of electrophoretic mobility of BSA versus gel density (%T) at constant 2%C. The straight lines were calculated from the data by means of least squares regression. (Reproduced from Thorun W (1971) *Zeitschrift für Klinische Chemie und Klinische Biochemie* 9: 3–11.)

ways of overcoming charge effects. In one, a relatively large amount of charged ligand, such as sodium dodecyl sulfate (SDS), is bound to the protein, effectively swamping the initial charges present on the protein molecules and giving a quasi constant charge-to-mass ratio. However, in SDS electrophoresis proteins are generally dissociated into the constituent polypeptide subunits and the concomitant loss of functional integrity and antigenic profiles cannot be prevented. Therefore, the size of the original, native molecule has to be evaluated in the absence of denaturing substances.

In the second method for  $M_r$  measurements, this can be done by relying on a mathematical canceling of charge effects following measurements of mobility of native proteins in gels of different concentrations. This is the 'Ferguson plot' described above:

$$\log R_m = \log Y_0 - K_R T \quad [2]$$

However, this approach to  $M_r$  determination has never found widespread application as it is laborious, tedious, and expensive in terms of time and sample material.

This leads on to a third method for molecular size measurements: the use of gels of graded porosity. The principle of the technique is shown in **Figure 4**; it is seen that, given enough time (at least  $10 \text{ kV} \times \text{h}$ ) the mobility of most serum proteins becomes constant and eventually ceases as each constituent reaches a

**Figure 4** Plots of the mobilities of serum proteins against time using pore gradient gels. Solid lines: uniform cross-linking (5%C); dashed lines: variable cross-linking. (Reproduced with permission from Margolis J and Wrigley CW (1975) *Journal of Chromatography* 106: 204–210; © Elsevier.)

gel density region in which the average pore size approaches the diameter of the protein (pore limit). Thus, the ratio between migration distance of a protein to that of any other becomes a constant after the proteins have all entered a gel region in which they are subjected to drastic sieving conditions. This causes the electrophoretic pattern to become constant after prolonged runs in a gel gradient. The gel concentration at which the migration rate for a given protein becomes constant is called the 'pore limit': if this porosity is properly mapped with the aid of a suitable set of marker proteins, then it is possible to correlate the migration distance to the molecular mass of any constituent in the mixture.

After the electrophoretic run has been performed, and the proper experimental data gathered, there are two basic ways for mathematical handling of data: two-step and one-step methods. In the former case, the migration distance of proteins is plotted against the square root of electrophoresis time. If now the slopes of the various regression lines thus obtained are plotted against the respective molecular masses, a good linear fit is obtained, which allows  $M_r$  measurements

of unknown proteins between  $2 \times 10^5$  and  $10^6$ . The shape of the proteins (globular or fibrillar), their carbohydrate content (up to 45%), and their free electrophoretic mobilities (between  $2.1$  and  $5.9 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) do not seem to be critical for proper  $M_r$  measurements by this procedure. In the one-step methods, when  $\log M_r$  is plotted versus  $\%T'$  or  $D'$ , a linear regression line is obtained, which allows accurate estimation of  $M_r$ s of unknown proteins. The following empirical equations, linking the above parameters, have been derived:

$$\log M_r = -e'\%T + y' \quad [3]$$

$$\log M_r = -e''D' + y'' \quad [4]$$

where  $-e'$  and  $-e''$  represent the slopes of the various regression lines while  $y'$  and  $y''$  (i.e., the  $y$ -intercepts) are indeed a single point at which the gel concentration equals the starting gradient concentration. The  $\log(M_r \text{ max})$  or  $\log(R_s \text{ max})$  corresponding to this concentration is of the order of  $1.3 \times 10^6 \text{ Da}$  ( $R_s = 9.3 \text{ nm}$ ). The correlations  $\log M_r - \%T'$  or  $\log M_r - D'$  are not significantly altered by the duration of electrophoresis. Therefore, a constant  $M_r$  value should be obtained for a stable protein, no matter how long electrophoresis is performed. It has also been demonstrated that the same mathematical relationship given above ( $\log M_r$  versus  $D'$ ) is also applicable to SDS electrophoresis in linear polyacrylamide gel gradients.

## Sodium Dodecyl Sulfate Electrophoresis

SDS electrophoresis was the next logical step after disk electrophoresis. While the latter discriminates macromolecules on the basis of both size and surface charge, SDS electrophoresis fractionates polypeptide chains essentially on the basis of their size. It is therefore a simple, yet powerful and reliable method for molecular mass ( $M_r$ ) determination. In 1967, it was first reported that electrophoretic migration in SDS is proportional to the effective molecular radius and thus to the  $M_r$  of the polypeptide chain. This result means that SDS must bind to proteins and cancel out differences in molecular charge, so that all components then migrate solely according to size. Surprisingly large amounts of SDS appear to be bound (an average of 1.4 g SDS per gram of protein), which means that the number of SDS molecules bound is of the order of half the number of amino acid residues in a polypeptide chain. This amount of highly charged surfactant molecules is sufficient to overwhelm effectively the intrinsic charges of the polymer coil, so that their net charge per unit mass

becomes approximately constant. If migration in SDS (and disulfide reducing agents, such as 2-mercaptoethanol, in the denaturing step, for a proper unfolding of the proteins) is proportional only to molecular mass, then, in addition to canceling out of charge differences, SDS also equalizes molecular shape differences as well (e.g., globular versus rod-shaped molecules). This seems to be the case for protein-SDS mixed micelles: these complexes can be assumed to behave as ellipsoids of constant minor axis ( $\sim 1.8 \text{ nm}$ ) and with the major axis proportional to the length in amino acids (i.e., to molecular mass) of the protein. The rod length for the 1.4 g SDS/g protein complex is of the order of 0.074 nm per amino acid residue.

The protein sample ( $\sim 1 \text{ mg ml}^{-1}$ ) is usually denatured in  $100 \text{ mmol l}^{-1}$  phosphate pH 7.0, containing 1% SDS, 1% 2-mercaptoethanol, 5–10% sucrose (for incrementing the sample density for gel loading purposes) and traces of bromophenol blue (as a tracking dye for monitoring boundary formation in discontinuous systems and for checking run termination). After heating at  $100^\circ\text{C}$  for 5 min, the sample is usually deposited in pockets preformed in the gel slab. Originally, continuous gel matrices and buffers were used, but today discontinuous buffers and gel phases are preferred, since they produce sharper bands and better resolution. In SDS electrophoresis, the proteins can be prelabeled with dyes that covalently bind to its  $-\text{NH}_2$  residues. They can be conventional (like the blue dye Remazol) or fluorescent, like dansyl chloride, fluorescamine, *o*-phthaldialdehyde, and MDPF (2-methoxy-2,4-diphenyl-3(2 H)-furanone). Prelabeling is compatible with SDS electrophoresis, as the size increase is minimal, but would be anathema in disk electrophoresis or isoelectric focusing, as it would generate a series of bands of slightly altered mobility or pI from an otherwise homogeneous protein. Among post-labeling techniques, silver staining has become quite popular, since the amount of detectable protein per band can be as little as 1 ng, and this allows resolution of bands differing by only 300 Da in size. An example of SDS electrophoresis of prion proteins is given in Figure 5.

Two classes of proteins show anomalous behavior in SDS electrophoresis: glycoproteins (because their hydrophilic oligosaccharide units prevent hydrophobic binding of SDS micelles) and strongly basic proteins (e.g., histones) (because of electrostatic binding of SDS micelles through their sulfate groups). The first can be partially alleviated by using Tris-borate buffers at alkaline pH, which will increase the net negative charge on the glycoprotein, thus producing migration rates well correlated with molecular size.

**Figure 5** Analysis of prion proteins by SDS-PAGE. Extreme left and right lanes: prion protein (PrP) purified by affinity capture with specific antibodies; brain homogenate; two tracks with cerebrospinal fluid (Liq. and Liq. H); M: molecular mass markers. Gel: 7.5–20% *T* porosity gradient, with a Laemmli's discontinuous buffer system. Staining: Coomassie Brilliant Blue. (Unpublished experiments with Castagna A, Monaco S, and Zanusso P.)

Migration of histones can be improved by using pore gradient gels and allowing the polypeptide chains to approach the pore limit.

## DNA Sequencing

The first step in sequencing a purified DNA molecule is to break it specifically into a number of well-defined species with a restriction endonuclease and then to select and prepare the piece to be sequenced. The second step is to prepare families of related fragments from this species. For this, two basic methods are available: (1) the chain terminator approach of Sanger and (2) the chemical or Maxam and Gilbert DNA sequencing method. Once this family of fragments has been produced by either method, their analysis can be performed by PAGE, in matrices capable of resolving oligonucleotide chains with one end identical and the other end varying in length by a single nucleotide. The resulting map is interpreted by a computer-linked gel scanner and data handling equipment. The gels used for sequencing are usually thin (0.2–0.4 mm) and rather large, e.g., 25 cm × <1 m; this enables a sequence of ~400 nucleotides to be read off a single polyacrylamide gel slab.

The chain terminator method depends on the primed synthesis of a complementary radioactive copy of a single-stranded DNA template by a DNA polymerase. The base-specific ends of the oligodeoxynucleotides thus synthesized are produced by incorporating 2',3'-dideoxynucleoside triphosphates into the newly synthesized DNA. The dideoxy analogs lack the 3'-hydroxyl group necessary for the formation of the next phosphate bond during chain growth, so that whenever a dideoxynucleotide is incorporated into the growing polynucleotide chain, growth stops. During normal chain extension, all four deoxynucleoside triphosphates are available to DNA polymerase. Usually one of them has a radioactive ( $^{32}\text{P}$ ) phosphate, allowing the newly synthesized DNA to be labeled. If one of these is completely replaced by its dideoxy analog, chain growth will stop at the first site of incorporation of the dideoxynucleotide. Since in the incubation mixture the dideoxy analog is present with some amount of its normal deoxynucleoside triphosphate counterpart, a partial incorporation of the former occurs at each possible site. Thus, by adding one of the dideoxy analogs to each of the four separate incubation mixtures, four different groups of fragments, ending at a particular base, are produced. The other end of all the fragments is identical, so that parallel

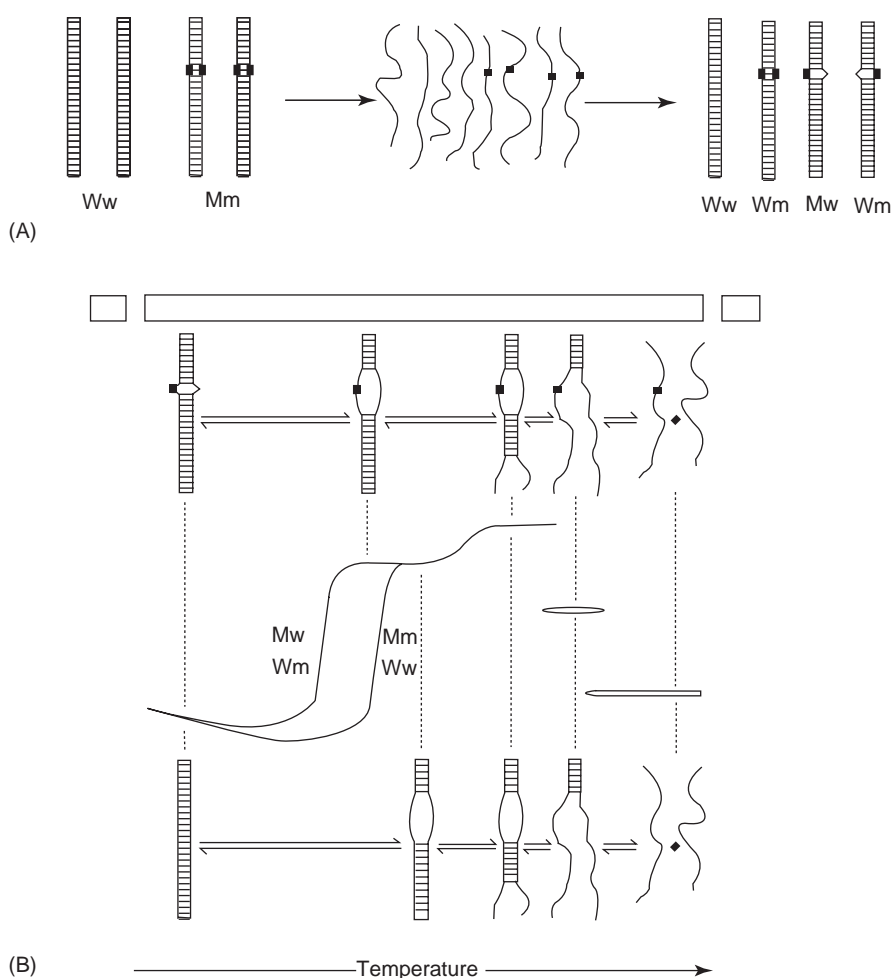

size-fractionation of the denatured fragment groups by analytical PAGE allows the sequence to be deduced.

In alternative to endpoint methods with radionucleosides, it is possible to use four different fluorophores, having four different emission wavelengths, for tagging the primer. The purified DNA fragment to be sequenced is thus divided into four aliquots, each of which is then confronted with a primer, tagged with one of the four fluorophores. The primer extension is then obtained with the Klenow fragment of DNA polymerase I from *Escherichia coli*, or with T7 polymerase or Taq polymerase. The four reaction mixtures are then electrophoresed simultaneously in a gel equipped with a detection system, which comprises a scanning argon laser beam, which sweeps the gel at a fixed position, perpendicular to the band

migration. The excited fluorescence is converted and amplified by a photomultiplier tube, and the digital signal is analyzed by a computer.

## Temperature Gradient Gels

This is a unique mode of performing electrophoresis under conditions of continuous conformational changes. This method is especially suitable for nucleic acid analysis. A 1-mm-thick gel slab is made to contain a long trench at the side of the negative electrode. A linear temperature gradient is established perpendicular to the direction of the electric field. Thus, as the nucleic acid sample is moving toward the opposite electrode, it will migrate against progressively increasing temperatures in the gel.

**Figure 6** Example of detection of mutations in form of mismatches in ds-DNA by temperature gradient electrophoresis. (A) Denaturation–renaturation cycle, with a schematic representation of the mechanism demonstrating that a base-pair exchange (■–■) is transferred into a mismatch (■>, <■). (B) Schematic drawing of the transition curves, showing that the denaturation temperature of the segment, which carries the mutation is lowered significantly. W, wild-type sequence, (+) strand; w, wild-type sequence, (–) strand; M, mutated sequence, (+) strand; m, mutated sequence, (–) strand; ♦, point mutation. (Reproduced with permission from Riesner D, Henco K, and Steger G (1991) *Advances in Electrophoresis*, vol. 4, pp. 169–250; VCH.)

A double-stranded (ds) DNA will undergo two highly cooperative conformational transitions: one from the native, base-paired state to a partially denatured state (in general sigmoidal) and the second one to the totally denatured state after strand separation. This helix-coil transition of ds nucleic acids can be described quantitatively by statistical thermodynamics. This method can be applied to a number of analyses: e.g., detection of mutations in the form of base-pair exchanges in ds-RNA and DNA, analysis of cDNA clones with point mutations from site-directed mutagenesis, detection of mutations in the form of mismatches in ds-DNA. An example on the last case is given in **Figure 6**: if a mutant ds-DNA is present in the same solution as the wild-type ds-DNA, hybrids between both can be formed in a denaturation-renaturation cycle (**Figure 6A**). In such an event a mismatch can form in the double helix at the site of mutation. Mismatches always decrease the  $T_m$  value and will be easily detected by electrophoresis in a thermal gradient by a sigmoidal transition occurring at a lower temperature as compared with the wild-type (**Figure 6B**). In general, one expects, from this type of analysis, in the presence of a point mutation,

the formation of four zones: two homo- (Ww and Mm) and two hetero- (Mw and Wm) duplexes. This kind of analysis is known under the acronym DIGE (denaturing gradient gel electrophoresis) and it is better performed in presence of the so-called GC-clamps, i.e., of 30–40 base pair-long GC regions added at one extremity of the amplified DNA region under analysis. Such clamps prevent total strand separation, due to high resistance to denaturation (either chemical or thermal) of GC-rich regions and thus permit the detection of the four zones of homo- and hetero-duplexes. It should be noted that DIGE can be performed not only in temperature gradients, but also in chemical denaturing gradients, such as gradients from 0 to 8 mol l<sup>-1</sup> urea, with identical results. The latter gradients are in fact preferred due to the much easier experimental setup. As a latest evolution of DIGE, a double gradient technique has been reported, by which the denaturing gradient (either thermal or chemical) is co-linear with a porosity gradient in the gel matrix. The latter gradient is needed to recompact the diffuse bands (especially of hetero-duplexes), which melt over a broader range of denaturants and are thus diffuse.

**Figure 7** Analysis of the 1-kb ladder by capillary zone electrophoresis. Conditions: coated capillary of 100  $\mu$ m i.d., 47.4 cm length, filled with 4.5% polyacrylamide strings in 100 mmol l<sup>-1</sup> Tris–borate–EDTA, pH 8.0. Sample: a 0.25  $\mu$ g ml<sup>-1</sup> solution of the 1-kb ladder was injected electrophoretically for 3 s at 4 kV; run: at 4 kV and 11.4  $\mu$ A. The numbers on each peak represent the length of each fragment, in number of bases. Tris, 2-amino-2-hydroxymethylpropane-1,3-diol; EDTA, ethylenediaminetetraacetic acid.

## Physical versus Chemical Gels

This is perhaps the newest and most exciting development in zone electrophoresis. While so far most runs have been performed in 'chemical' gels, cross-linked (see **Figure 1**) so as to form a fixed chain distribution in space, it appears that analogous results can be obtained in 'physical' gels (or polymer networks), i.e., in viscous solutions of long, linear strings of monomer, in the absence of cross-linker. Sieving in 'physical' gels is just as effective as in 'chemical' gels, provided that the polymer solution is above the entanglement threshold, which, for polyacrylamides, is set at  $\sim 0.5\%$  concentration. The larger the object to be separated, the more dilute will be the polymer solution and vice versa. Thus, for separating large DNA fragments, up to 22 kbp, a 4.5% polymer concentration will be adequate. But, for DNA sequencing gels, up to 100 bp, a 10% polymer solution will be required. For running native proteins, solutions up to 15% and higher are often required. The advantage of physical gels, especially in capillary zone electrophoresis, is the possibility of filling the separation chamber (often of very narrow bore, e.g., 20  $\mu\text{m}$  i.d.) without trapping air bubbles. In addition, 'physical' gels can be reused several times (up to 50) without trapping or precipitating the sample at the injection port, a phenomenon that occurs regularly in 'chemical' gels, due to the large fiber diameter and thus to a greater surface available for sample adsorption and trapping. **Figure 7** shows the power of separation in physical gels, when analyzing a large spectrum of DNA sizes, ranging from as little as 75 bp up to 12 kbp.

## Two-Dimensional Gels

P G Righetti, University of Verona, Verona, Italy

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Two-dimensional, polyacrylamide gel electrophoresis (2D PAGE) is an open assay approach, which permits the separation and detection of proteins from a wide variety of sources without the need for any prior

knowledge of function. Two-dimensional PAGE is capable of profiling many thousands of proteins on a single matrix with exquisite resolution, separating very discrete isoforms differing by post-translational modifications as subtle as a single deamidation event. The basic elements for the development of 2D PAGE were laid out in the mid-1960s, with the description of isoelectric focusing (IEF), by which proteins would be separated essentially on the basis of their net charge (at a given value of their titration curve, the

isoelectric point, pI). Almost coeval was the discovery of sodium dodecyl sulfate (SDS) electrophoresis, by which surfactant-laden proteins would be separated essentially via their mass, rather than by combination of mass and charge effects, as customary in conventional zone electrophoresis. Now, the elements for the next major quantum leap were laid out on the table. In the mid-1970s, O'Farrell took advantage of this previous know-how and reported the creation of 2D maps, by combining orthogonally a first dimension, based on pure charge fractionation, with a second dimension, based on size discrimination of denatured and fully dissociated polypeptide chains. Although the original O'Farrell approach was very advanced at the methodologically level, it took, nevertheless, many years of developments and refinements for bringing the technique to the present-day highly sophisticated level. Instrumental to that were major contributions from the field of informatics, which had to develop new algorithms for mapping the 2D space, acquiring the images, cleaning the background, matching different maps among themselves. Informatics has also greatly contributed by laying out a format for protein databases, which today represent a formidable tool in protein characterization. Another major contribution was the introduction, in 1982, of immobilized pH gradients (IPG), which offered a new, most powerful view of the field, guaranteeing much increased resolution and much higher reproducibility in spot position. Just as fundamental was the introduction, in the early 1990s, of mass spectrometry (MS) as a tool for sequencing small peptides and for identifying proteins. Up to the present, 2D mapping was a synonym for proteome analysis, although today a host of 2D chromatographic approaches (or hybrid, hyphenated chromatographic and electrophoretic techniques) are rivaling with the old, well-ingrained 2D PAGE. With a proviso, though: most chromatographic methods start with a fully digested tissue extract, and thus have to deal with a tremendously heterogeneous peptide population; 2D maps, on the contrary, deal only with intact polypeptide chains, as a genuine snapshot of the proteomic patrimony of the tissue under investigation.

## Sample Solubilization and Pretreatment

Figure 1 shows what is perhaps the most popular approach to 2D map analysis today. The first dimension is preferably performed in individual IPG strips, laid side by side on a cooling platform, with the sample often adsorbed into the entire strip during

**Figure 1** Pictorial representation of the steps required for obtaining a 2D map, with the first dimension typically done in IPG strips, followed by equilibration of the focused strips in SDS-interfacing solution and finally by the second dimension run in SDS-PAGE.

rehydration. At the end of the IEF step, the strips have to be interfaced with the second dimension, almost exclusively performed by mass discrimination via saturation with the anionic surfactant SDS. After this equilibration step, the strip is embedded on top of an SDS-PAGE slab, where the second-dimensional run is carried out perpendicular to the first-dimensional D migration. The 2D map displayed at the end of these steps is the stained SDS-PAGE slab, where polypeptides are seen, after staining, as (ideally) round spots, each characterized by an individual set of pI/ $M_r$  coordinates (pI, isoelectric point;  $M_r$ , molecular mass).

Instrumental to the success of 2D PAGE is sample treatment prior to any electrophoretic step. To start with, one should recall that, when cells are lysed,

hydrolases (phosphatases, glycosidases, and especially proteases) are in general liberated or activated. In the presence of chaotropes, glycosidases and phosphatases are quickly denatured, but the denaturation of proteases might have slower kinetics. This could result in much altered spots in the subsequent 2D analysis, to the point that no band recognition is any longer possible. Proteases are in general inhibited when the tissue is disrupted directly in strong denaturants, such as  $8 \text{ mol l}^{-1}$  urea, 10% trichloroacetic acid, or 2% SDS. But there are still two major problems: (1) some proteases might be more resistant to denaturation than the majority of the other cellular proteins, so that, while the former have been unfolded, proteases might have some time for attack before being denatured too; (2) in other cases (e.g., red blood cells, RBCs) the cells might have to be lysed under native conditions, in order to eliminate some cellular components, so that there is ample time for strong proteolytic aggression. In any event, proteases are less active at lower temperature, which is why, during cell disruption, low temperatures ( $2\text{--}4^\circ\text{C}$ ) are in general recommended. In addition, most tissue proteases are inactive above pH 9.5, so that proteolysis can often be inhibited by preparing the sample in Tris-free base, sodium hydrogen carbonate, or basic carrier ampholytes (CAs) at pH values  $\sim 10$ . Some proteases, however, might retain activity even when all the above precautions are taken. Thus, as a safety precaution, it is advisable to use a cocktail of protease inhibitors. Such combinations are available from a number of commercial sources and in general comprise both chemical and proteinaceous inhibitors (e.g., phenylmethylsulfonyl fluoride, ethylenediaminetetraacetic acid, aprotinin). The importance of safeguarding the sample against accidental proteolytic attack during preparation should never be underestimated. A case in point is the dramatic example of 2D maps of RBC membranes, given in **Figure 2**, when processed in the absence of presence of proper inhibitor cocktails. The primary concern when preparing RBC membranes for electrophoresis is to remove hemoglobin, which is present at extremely high levels in the RBC and can cause severe streaking in 2D maps. Most of the procedures in the literature involve washing the RBCs in physiological buffered saline followed by lysis and washing in hypotonic buffer. However, there has been a lack of attention paid to the activation of proteases upon RBC lysis. It is seen here that, in the absence of protease inhibitors, a peptide map (B) is generated, rather than a map of intact protein species (A).

The second major advance in 2D maps has been a much improved solubilization cocktail, after the classical O'Farrell mixture, comprising  $9 \text{ mol l}^{-1}$

**Figure 2** Two-dimensional map of RBC membranes: (A) treated with protease inhibitors during the lysis and washing steps; (B) control, untreated with protease inhibitors. Note, in this last case, the massive proteolytic action. The numbers at the gel top indicate the pH interval (pH 3–10, nonlinear). (Reproduced with permission from Olivieri E, Herbert B, and Righetti PG (2001) The effect of protease inhibitors on the two-dimensional electrophoresis pattern of red blood cell membranes. *Electrophoresis* 22: 560–565.)

urea, 2% Nonidet P-40, 2%  $\beta$ -mercaptoethanol, and 2% CAs. Membrane proteins require a much stronger solubilizing power, which has been ensured, over the years, by resorting to more powerful mixtures. The consensus cocktail in vogue today comprises  $5\text{--}7 \text{ mol l}^{-1}$  urea,  $2\text{--}3 \text{ mol l}^{-1}$  thiourea, and 2% amidosulfofetaines. Thiourea, in view of its marked hydrophobicity (it is soluble in water only up to  $1 \text{ mol l}^{-1}$  level; thus urea acts as a co-solvent), dramatically increases the solubilizing power of this mixture. So does the surfactant amidosulfofetaine, a modified dodecylsulfofetaine. This last class of surfactants had been found to be by far the class

with the highest solubilizing potency, perhaps due to their resemblance with the anionic SDS moiety, but it was precipitated by levels of urea  $>4 \text{ mol l}^{-1}$ . By breaking the tail hydrophobicity with the introduction of an amido group, the sulfobetaines were made compatible with levels of urea up to  $10 \text{ mol l}^{-1}$ .

Another factor that influences protein solubilization is the choice of the reducing agent. It is agreed that to solubilize a complex mixture of proteins in preparation for IEF, it is necessary to completely break inter- and intrachain disulfide bonds by reduction. This is commonly achieved using cyclic reducing agents, such as dithiothreitol or dithioerythritol, which are added to the solubilizing cocktails in large excess ( $20\text{--}40 \text{ mmol l}^{-1}$ ), so as to shift the equilibrium toward oxidation of the reducing agent with concomitant reduction of the disulfide bridges. Because this is an equilibrium reaction, loss of the reducing agent through proteins migration away from the sample application zone, during the first IEF dimension run, can result in reoxidation of free Cys, an effect that has two possible consequences: horizontal streaking and formation of spurious bands due to scrambled  $\text{--S--}$  bridges and their cross-linking various polypeptide chains. This situation would be even worse when using  $\beta$ -mercaptoethanol, which has a lower  $pK$  value; thus, it will be more efficiently depleted in the alkaline region and will form a concentration gradient toward pH 7, with a distribution in the gel according to its extent of ionization at a given pH value along the IEF strip. Recently, it was demonstrated that the use of a non-charged reducing agent, such as tributyl phosphine (TBP), greatly enhanced protein solubility during the IEF and resulted in a much improved transfer to the second dimension. It is worth noting that the contribution of thiourea to solubility follows a different route from that of TBP: the first increases the chaotropic capability of the sample solution, while TBP ensures the necessary reducing conditions during the IEF stage. Curiously, though, whereas the need for adding a reducing agent has been recognized since the early days of O'Farrell, up to recent times no 2D PAGE protocol reported the other complementary step, i.e., alkylation of free  $\text{--SH}$  groups following their reduction. Failure to reduce and fully alkylate proteins prior to the first dimension can result in a large number of spurious spots in the alkaline pH region, due to 'scrambled' disulfide bridges among like and unlike chains. This potential series of artifactual spots can comprise dimers, trimers, up to nonamers, and perhaps higher oligomers. This statement can be easily supported by the data in **Figures 3A** and **3B**, which refer to 2D maps of globin chains. Map (B), which was obtained following

reduction and alkylation prior to the first dimension, presents the expected simple pattern, composed of a few spots aligned at  $\sim 16 \text{ kDa}$ ; the map in (A), on the other hand, was obtained without alkylation, which explains the presence of a number of strings, which MALDI-TOF-MS (matrix-assisted laser desorption ionization time-of-flight MS) identified as multiples of the above  $M_r$ .

Another important problem is the proper choice of the alkylating agent. By far the most popular chemical, up to the present, has been iodoacetamide. Yet, this compound, in presence of thiourea, is quickly destroyed, thus jeopardizing the alkylation reaction. An alternative solution would be to alkylate not with an iodinated agent, but with acrylamide, by exploiting the reactivity of  $\text{--SH}$  group toward addition to double bonds. An even better solution is to alkylate at neutral pH with 2- (or 4-)vinylpyridine, since this reagent has been found to offer 100% reactivity coupled to 100% specificity. The specificity is ensured by lowering the reaction pH from 9.5 (as customary for alkylation of the  $\text{--SH}$  group) to pH 7, where Lys and other side chains cannot possibly react; the sustained reaction is ensured by the fact that this pH value is half a way between the  $pK$ s of the reactants, thus providing fractional positive and negative charges onto the two reactants. **Figure 4** shows that indeed, with vinylpyridine, 100% alkylation of all reacting  $\text{--SH}$  groups is obtained, contrary to alkylation with other chemicals.

## The First Dimension

In the past, the vast majority of 2D maps were run by conventional IEF with soluble CAs for the first dimension. However, due to poor reproducibility in both gradient shape and CA synthesis, there has been a marked shift toward the use of IPGs. Precast, dried Immobiline gels, encompassing a number of ranges, are now available from Amersham Pharmacia Biotech, Bio-Rad, and Proteome Systems. They all contain 4%T (total monomer concentration, expressed as grams acrylamide + grams Bis per 100 ml of solution) and they span the following narrow pH ranges: 3.5–4.5; 4.0–5.0; 4.5–5.5; 5.0–6.0; 5.5–6.7. In addition, there are a number of wide pH ranges: 4–7L; 6–9; 6–11; 3–10L, and 3–10NL (L = linear; NL = nonlinear). Some of them are available in 7, 11, 13, and 18 cm in length, whereas all the narrow ranges are cast only as long (18 cm) strips (more recently, the trend is toward longer IPG strips, e.g., 24 cm in length). All of them are 3 mm wide and, when reswollen, 0.5 mm thick (gel layer). Precast, dried IPG gels in alkaline narrow ranges should be

**Figure 3** Two-dimensional maps of globin chains: (A) reduced but nonalkylated sample; (B) reduced and alkylated sample prior to the focusing step. Note, in panel A, the presence of higher-order homooligomers of  $\beta$ -chains, detected up to the dodecamer level. Note additionally the presence of homodimers of  $\alpha$ -chains, as well as of a heterodimer  $\alpha$ - $\beta$ . Note, in panel B, the complete removal of all higher-order oligomers and the detection of minor components of RBC lysates, such as carbonic anhydrase and thioreduction reductase, which would have been hidden under the string of dimers in nonalkylated samples. (Reproduced with permission from Herbert B, Galvani M, Hamdan M, *et al.* (2001) Reduction and alkylation of proteins in preparation of two-dimensional map analysis: why, when and how? *Electrophoresis* 22: 2046–2057.)

handled with care, because at high pHs the hydrolysis of both the gel matrix and the Immobiline chemicals bound to it is much more pronounced. Such gels, when cast onto a Gel-Bond PAG foil, have dimensional stability and can be handled quite safely. The fact that they are rather dilute (4%T) improves their performance, since there is less steric hindrance to large proteins, thus permitting shorted focusing times. In addition, if required, even more dilute matrices can be cast, down to  $\sim 3\%$ T (with variable amounts of cross-linker, in general from 3–5%C) (C, grams of cross-linker per 100g of total monomers). Although the most popular cross-linker is Bis

(*N,N'*-methylene bisacrylamide), good performance is also given by adopting bisacrylylpiperazine as crosslinking agent, since the latter is more stable to hydrolysis and is immune from the strongly yellowish backgrounds produced during silver staining in bis-gels. Routinely, IPG gels are cast to provide an average buffering power ( $\beta$ ) of 3 mequiv. $l^{-1}$ , which corresponds to total Immobiline molarities in the gel (buffering and titrant ions) of the order of 10 mmol $l^{-1}$ . However, when working at pH extremes (e.g., in the pH 2.5–4.5 and 9.5–11.5 intervals), this molarity should be doubled, so as to counteract the  $\beta$  power of the bulk solvent (water).

Figure 3 (Continued).

Since the IPG strips are supplied as dried films, there are different types of sample loading, as illustrated below.

**Pulse Loading**

This is the method typically adopted in all fractionation techniques, including chromatography, since due to entropic forces tending to dissipate the sample zone, the latter have in general to be applied as a very thin zone. This, of course, does not hold true for any focusing procedure, which reaches steady-state conditions. Nevertheless, it has been customary, for years, to apply the sample (especially in the old procedure of CA-IEF) in pockets precast in the gel, or in surface basins or adsorbed onto granulated materials (e.g., Sephadex, Paratex films, and the like). Sample cups did seem to offer a valid alternative to loading, since they permitted higher volume loadings (up to 100 µl) than with any other conventional means. To this purpose, Amersham Pharmacia Biotech devised a bar holder, able to position of battery of cups on a linear array of pre-hydrated IPG strips. This holder would gently press the cups against the gel surface, so

as to prevent sample leakage; each cup would then be filled with the desired volume of any sample. This method too is being used less and less, since it was found that significant amounts of proteins were lost at the application point, due to protein aggregation and precipitation as they migrated from the free liquid phase into the gel, with the ultimate result being poor resolution and ‘underloading’. This effect has been explained as a concentration phenomenon occurring at the gel-sample interface, where proteins massively accumulate as they are dramatically slowed down in their transit from a liquid phase to a gel phase. At this interface also anomalous ionic boundaries will form and the two concomitant phenomena would favor protein aggregation and precipitation.

**In-Gel Rehydration Loading**

This method is today by far preferred since it facilitates higher protein loads and reduces focusing times. With this technique, the dehydrated IPG strip is directly reswollen with the protein sample dissolved in the rehydration solution (notice that, in this last case,

**Figure 4** MALDI-TOF mass spectra of bovine  $\alpha$ -lactalbumin after 1 h incubation with 2% amidosulfobetaine-14 and: (A) acrylamide, (B) 2-vinylpyridine, and (C) 4-vinylpyridine. In all cases the reaction has been carried out at pH 7.0. Note, in both panels B and C, a single reaction channel of LCA with 2VP and 4VP, respectively. The higher-order peaks ( $m/z$  15 248 and 15 468 in B and C) represent adducts LCA with the MALDI matrix, sinapinic acid (unpublished data).

the same solution is used to solubilize the protein and rehydrate the IPG strip). After a suitable rehydration time ( $\sim 5$ – $6$  h), the IPG strip is ready for the first dimension IEF, with the proteins already uniformly distributed within the gel matrix. The clear advantage of in-gel rehydration is the large volume of samples that can be applied (up to  $450\ \mu\text{l}$  for a 18 cm long, 4 mm wide, 0.5 mm thick IPG strip) compared to  $100\ \mu\text{l}$  for conventional cup loading. The other major advantage is minimization of sample aggregation and precipitation: since the sample is diluted through the entire gel strip, no local, accidental build ups of proteins can occur. The third advantage of this protocol is that, due to dilution of proteins throughout the gel, much accelerated focusing protocols can be adopted, utilizing higher voltage gradients at the very start of the IEF/IPG run.

#### In-Gel Hydration Loading under a Low Voltage

This technique, also called active sample loading, is distinguished from the previous one (called passive), in that, during IPG strip rehydration, a gentle voltage gradient (typically 50 V) is applied, usually for the

entire duration of the reswelling (overnight). It is believed that this procedure would further facilitate sample entry. Recently, in fact, an interesting aspect of such active sample loading was reported: its ability to facilitate entry of high  $M_r$  proteins, such as spectrins, large (280 kDa for the  $\alpha$ -chains), filamentous proteins, which represent the major constituents of the cytoskeletal network underlying the RBC plasma membrane and are typically associated with band 4.1 and actin to form the cytoskeletal superstructure of the RBC plasma membrane.

## The Second Dimension

As shown in Figure 1, after the focusing step, the gel strip is transferred to a small test tube and bathed in a 10 volume excess of interfacing solution, for up to 15 min, so as to begin to saturate the isoelectric proteins with the SDS anionic surfactant. Thiol agents (e.g., DTT, TBP) can be omitted if the protein mixture has been properly reduced and alkylated prior to the focusing step. The equilibrated strips are then individually transferred to the upper edge of a

vertically standing SDS-gel cassette and cemented *in situ* by pouring over it a hot agarose solution. The overlay agarose recipe consists of 25 mmol l<sup>-1</sup> Tris base, 192 mmol l<sup>-1</sup> glycine, 0.1% SDS and 0.8% agarose (traces of bromophenol blue can be added, to mark the leading ion boundary during the SDS run).

The SDS-gel for the second dimension run can be cast in different ways. Quite a number of users prefer discontinuous gels, made after the classical Laemmli recipe. The stacking gel (usually 1–2 cm, long, made of a 3–4%T, 2.6%C, porous matrix) typically contains 125 mmol l<sup>-1</sup> Tris base, titrated to pH 6.8 with HCl, and 0.1% SDS. The running gel is in general a small pore gel, usually 10–12%T (2.6%C) cast in 375 mmol l<sup>-1</sup> Tris base, titrated to pH 8.8 with HCl, in presence of 0.1% SDS. The upper buffer reservoir (cathode) contains the terminating ion, 192 mmol l<sup>-1</sup> glycine, titrated with 25 mmol l<sup>-1</sup> Tris to pH 8.3, in the presence of 0.1% SDS. Since the anodic reservoir does not play any role in formation of the isotachophoretic train, it is usually filled with the same buffer employed as catholyte. In this experimental setup, the running gel is a constant-concentration matrix.

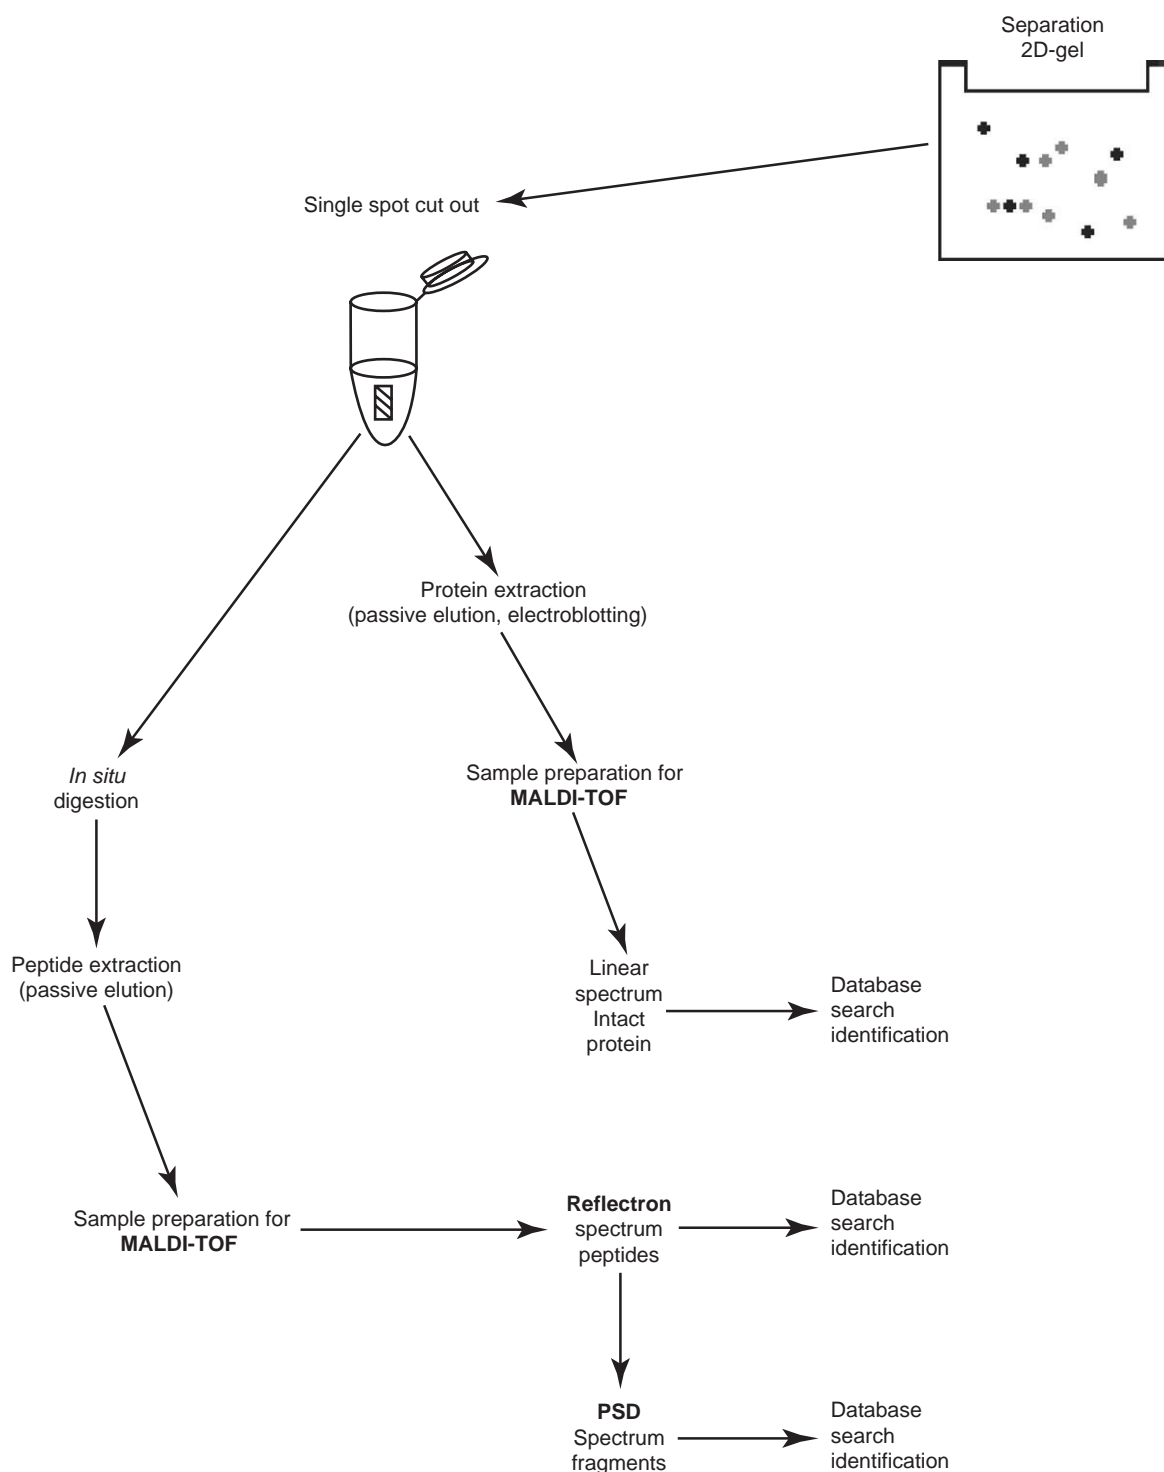

In another variant, the discontinuous Laemmli buffer is coupled to a gel of graded porosity as a running gel. In general, this last gel is cast with the aid of a two-vessel gradient mixer and the porosity gradient typically spans a 6%T to 20%T acrylamide gradient, although higher upper limits have been reported, up to 30%T in case of mixtures of rather small  $M_r$  proteins. A number of authors, though, deem the coupling of discontinuous buffers with a porosity gradient gel an extra burden in running the second dimension of 2D maps. Thus, in general, one or the other technique is used and rarely a combination of the two. It should be remembered, in fact, that porosity gradient gels also have a band-sharpening effect, since the leading edge of each zone is at any given time point migrating at a slower rate than its trailing edge, due to the higher sieving produced by the continuously diminishing pore size along the migration path.

The SDS gel slab, when stained at the end of the second dimension run, is the final 2D map displaying all the polypeptide chains spread randomly in the pI/ $M_r$  plane. For high sensitivity, this gel slab is in general stained with silver stains, deemed to be the most sensitive today available. However, as the 2D map has to be further processed, with elution of the various spot and their analysis by a variety of (MS methods, the silver stains employed cannot use glutaraldehyde or other aldehydes that could irreversibly modify the proteins, impeding proper

MS identification. MS-compatible silvering protocols have been described, but those markedly loose sensitivity, by as much as one order of magnitude. Thus, many laboratories prefer the use of colloidal Coomassie stains, which are fully compatible with MS analysis and have sensitivities similar to those of MS-compatible silver protocols. Fluorescent stains are also gaining momentum, in particular Sypro Ruby, a very high sensitivity stain, fully compatible with any MS approach. Imaging gels tagged with fluorophores, though, requires special (and costly) equipment, since regular gel scanners are not equipped with fluorescent-spot reading devices.

### Mass Spectrometry Analysis of Spots Eluted from 2D Maps

Obtaining a good 2D map, with nice, round spots well spread out in the 2D plane is certainly a good start, but by all means is only a part of the vast job required in proteome analysis, namely the discovery of the identity of as many polypeptide chains as possible in the map thus generated. Here, MS plays a fundamental role. **Figure 5** outlines one of the most popular procedures adopted in view of MS analysis. Single spots are cut out from the SDS gel slab (or from a blot onto, e.g., cellulose nitrate membranes) and eluted by various means or even digested *in situ*. In the last case, the eluted peptides are subjected directly to MS analysis, e.g., via MALDI-TOF. In the former case, the intact protein, once eluted, is injected directly in the mass spectrometer, which results in the  $M_r$  value of the undigested macromolecule. Obtaining both the precise  $M_r$  of the intact polypeptide chain as well as of its tryptic fragments greatly facilitates searching and identification of the species under analysis in the various databases. In order to improve data quality, a number of procedures are routinely adopted. First of all, when eluting a spot (or its tryptic fragments) directly from a gel piece, it is customary to adsorb the liquid onto a Zip-Tip, i.e., a tiny plastic cone of automatic pipettors filled with a C<sub>18</sub>-resin, for purification purposes. The tip is washed with water, so as to remove salt and other contaminants. The adsorbed polypeptides or peptides are then eluted with acetonitrile, a solvent fully compatible with subsequent MS analysis. Finally, it should be borne in mind that the data thus generated are subjected to a number of filtering procedures, so as to eliminate spurious data, such as those that could correspond to contaminants. As an example, all mass values that could be attributed to trypsin (or its fragments), Coomassie Blue adducts, chaperones, are automatically rejected. In addition,

**Figure 5** Scheme of the series of steps to be taken for identifying a polypeptide chain eluted from SDS-PAGE or from a 2D map. Note that, in addition to enzyme digestion and searching of databases via peptide masses (and partial peptide sequences obtained via PSD spectra), it is suggested here that an aliquot of the intact protein should be taken for assessment of native  $M_r$ . (From Hamdan M and Righetti PG, unpublished.)

each peptide list is compared with an analogous list obtained by analyzing a control spot, i.e., the eluate from a small gel segment that does not appear to contain any detectable polypeptide spot: in

this way, all peaks belonging to contaminants are rejected.

MS analysis can be exploited in more subtle ways, for obtaining not simply the precise mass of entire

**Figure 6** Example of sequence determination by PSD of a peptide of  $m/z$  2113.6 obtained by tryptic digestion of  $\beta$ -lactoglobulin B. On the basis of the PSD spectrum and the sequence determined, it was possible to assign this fragment to the amino acid region (106–124) of the protein chain. For a detailed explanation, see text. (Reproduced from Bordini E, Hamdan M, and Righetti PG (1999) Probing the reactivity of S–S bridges to acrylamide in some proteins under high pH conditions by matrix assisted laser-desorption/ionization. *Rapid Communication in Mass Spectrometry* 13: 1818–1827.)

proteins and of their tryptic fragments, but also for generating sequence data. For example, modern MALDI-TOF instruments are equipped with a device, called reflectron, which can select any peptide giving a strong signal and send it back to a reflectron detector placed near the ion source. This parental ion is thus subjected to a so-called post-source decay (PSD), by which it generates a series of ions produced by background collision. By properly searching for a series of  $y_n$ -fragment ions (i.e., those generated from the  $\text{NH}_2$  terminus of the parental peptide) it is possible to reconstruct the amino acid sequence of the said peptide. An example of this procedure is given in Figure 6, which reports the entire sequence of a peptide with  $m/z$  2113.6 obtained by tryptic digestion of  $\beta$ -lactoglobulin B.

## Quantitative Proteomics

2D map analysis, ultimately, should lead to quantitative profiling, i.e., to evaluation of up- and down-regulation in control and pathological tissues under analysis. Although up to present times this has been

done by profiling the mRNA expression, this does not seem to be quite satisfactory, considering that the correlation between the levels of mRNA and their expressed protein, at any given time in the life cell cycle, is quite poor, barely 0.4 (on a scale from zero to one). Comparison of 2D maps, separately run, by powerful software is one of the oldest and most popular methods in the electrophoretic approach to proteome analysis. For statistical significance three to five tissue samples, for each state, should be collected; the pooled samples will then be processed in preparation for 2D mapping. Four to five replicas of such 2D maps should be run simultaneously, so as to maximize spot reproducibility. From the replicas of the control and pathological states, master maps are produced, which contain all spots found in the individual gels. Spot intensities are normalized in each gel and a statistical test is adopted to evaluate significant differences between the control and treated groups, thus eliminating artifacts due to gel running. The comparison between the two master maps offers a clue about polypeptide chains whose expression is either up- or downregulated or which are newly expressed and unique to one or the other

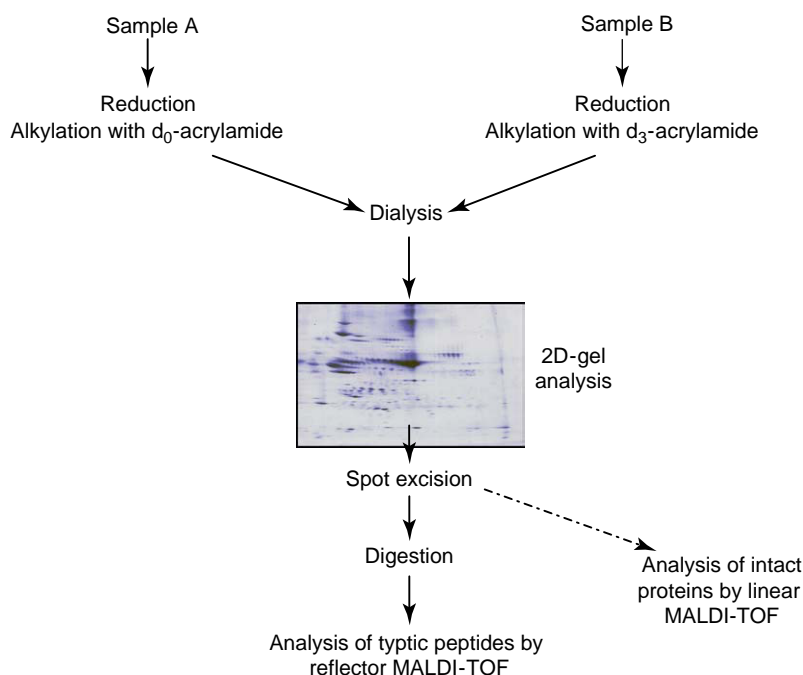

tissues. Once this differential analysis has been performed, all the spots of interest are excised, in-gel digested, and subsequently characterized by MS (e.g., via MALDI-TOF or liquid chromatography coupled to electrospray ionization).

This approach, amply used to the present, gives highly reliable results, but it is terribly time consuming and truly labor intensive. An alternative to this protocol is known under the acronym of DIGE, differential in gel electrophoresis. It is based on differential labeling with *N*-hydroxysuccinimide ester-modified cyanine fluors, the most popular couple being named Cy3 and Cy5. Cy3 is excited at 540 nm and has an emission maximum at 590 nm, while Cy5 is excited at 620 nm and emits at 680 nm. The two samples to be compared are separately labeled with either Cy3 or Cy5, which covalently modify Lys residues in proteins. These dyes have positive charges to replace the loss of charge on the  $\epsilon$ -amino group of Lys, and the masses of the dyes are similar to each other. The reaction is carried out so as to label only a few Lys residues per macromolecule. As long as the extent of the reaction is similar between the samples to be compared, the mass shift will be uniform and the pI should be essentially unaltered. Given the distinguishable spectra of the two fluorophores, the two samples can then be combined and run in a

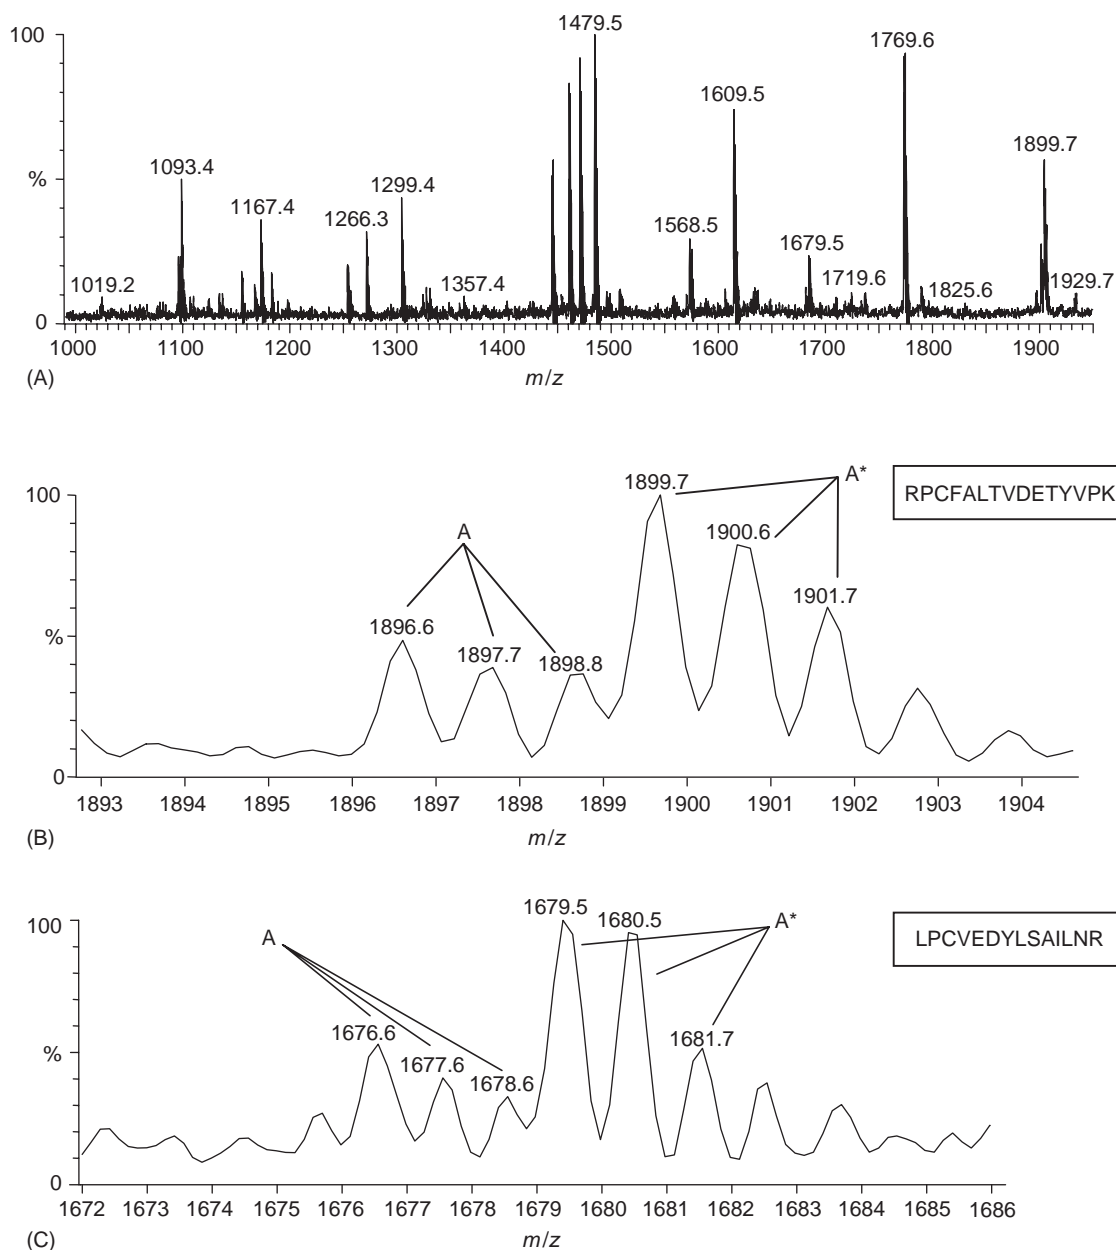

single 2D gel. The differences between the quantities of the individual proteins from each sample can then be determined using specialized 2D image analysis software. Since both samples to be compared are separated in a single gel, this eliminates gel-to-gel variation, resulting in improved spot matching. As a corollary, the number of parallel and replicate gels required for obtaining reliable results is greatly

**Figure 7** Comparison of 2D DIGE imaging and Sypro Ruby poststaining. Left panel: merged Cy dye image of HB4a lysate labeled with Cy3 (red) and HBC3.6 lysate labeled with Cy5 (blue). The same gel was poststained with Sypro Ruby (right panel). **Figure 8** Scheme for differential labeling of two samples with  $d_0/d_3$  acrylamide (alkylation of Cys residues). The central map refers to rat sera, labeled separately with either  $d_0$ - or  $d_3$ -acrylamide and mixed in a 30:70% ratio. (Reproduced from Gehanne S, Cecconi D, Carboni L, *et al.* (2002) Quantitative analysis of two-dimensional gel-separated proteins using isotopically marked alkylating agents and matrix-assisted laser desorption/ionization mass spectrometry. *Rapid Communications in Mass Spectrometry* 16: 1692–1698.)

**Figure 9** (A) Reflectron MALDI mass spectrum of an *in situ* digest of apo-transferrin taken from the 2D map of rat sera displayed in **Figure 4**, which were alkylated with  $d_0$ -acrylamide and  $d_3$ -acrylamide and mixed in a 30/70% ratio. (B) and (C) are two short intervals taken from (A), and are associated with the two indicated peptide sequences. (Reproduced from Gehanne S, Cecconi D, Carboni L, *et al.* (2002) Quantitative analysis of two-dimensional gel-separated proteins using isotopically marked alkylating agents and matrix-assisted laser desorption/ionization mass spectrometry. *Rapid Communications in Mass Spectrometry* 16: 1692–1698.)

reduced. Furthermore, fluorescence imparts the ability of detecting proteins over a much broader linear dynamic range of concentrations than visible gel stains. **Figure 7** gives an example of the DIGE technique, as applied to the analysis of breast cancer cells ErbB-2-transformed. Proteins that are present at equal levels in the two cell populations give a uniform violet hue. Proteins present in only one of the two tissues under comparison are either purely red or

blue in color, according to the Cy3/Cy5 label that they carry. Proteins up- and downregulated give intermediate hues that are properly quantified by specialized software.

In another variant for quantitative proteome analysis by 2D PAGE, one could exploit the technique of stable isotope tagging. In this approach, the labeling strategy involves light/heavy forms of the same tagging molecule. An example of such an approach

is the use of  $d_0/d_3$  acrylamide for blocking Cys residues in intact protein molecules. The basic steps in such an approach are depicted in **Figure 8**. Basically, relative quantification of individual proteins in two different samples is achieved by alkylating one sample with  $d_0$ -acrylamide, and the second with its  $d_3$ -counterpart; the two samples are then combined with predetermined ratios, dialyzed, and subjected to 2D gel electrophoresis. Following visualization of the separated proteins, each spot can be excised, digested with trypsin, and examined by MALDI-TOF. The relative quantification of a number of proteins would then be obtained by comparing the relative peak heights within a reflector MALDI spectrum of two adjacent isotopic envelopes that happen to differ by  $m/z = 3$ . The application of this approach to quantitation of various proteins within the 2D map of rat serum shown in **Figure 8** is illustrated below. The map in **Figure 8**, covering the pH 3–10 IPG interval, was obtained by mixing in different proportions two fractions of rat sera, the first (30%) being alkylated with  $d_0$ -acrylamide, and the second (70%) reacted with  $d_3$ -acrylamide. A representative example of a reflector MALDI spectrum that pertains to apotransferrin is given in **Figure 9(A–C)**. The spectrum of the entire digest is given in (A), whereas (B) and (C) display two short intervals of the same spectrum and show two isotopic distributions marked A and A\* in which a difference of 3 Da in the  $m/z$  values of the corresponding peaks is clearly evident. A database search yielded the two indicated peptides, each of which contains a single cysteine. Considering the relative peak heights in both isotopic distributions, a ratio of 34:66 was obtained, which is in good agreement with the labeling ratio 30:70 prior to 2D separation.

The methodology of 2D mapping, for proteome research, has been extensively developed, it is highly reproducible and quite standardized, and surely appears to be one of the best methods still available, at present time, for analyzing very complex tissue extracts, with the ability of displaying up to 12 000 spots in large format slabs, detected by autoradiography, a resolution unmatched by any other separation technique. Yet, on the horizon, seems to be rising the star of multidimensional (as pompously

called, in reality two-dimensional) chromatography, coupling, e.g., a strong cation exchanger with a RP-LC (reversed phase, liquid chromatography). With a proviso, though: most 2D chromatography approaches do not analyze the intact proteome (as 2D electrophoresis does) but a tryptic digest of the solubilized protein. This enormously increases the sample complexity, e.g., up to half a million peptides from a mixture of 10 000 proteins, thus calling for special affinity techniques able to reduce sample complexity.

## Introduction

This chapter deals with detection and exploitation of noncovalent reversible molecular interactions during

is the use of  $d_0/d_3$  acrylamide for blocking Cys residues in intact protein molecules. The basic steps in such an approach are depicted in **Figure 8**. Basically, relative quantification of individual proteins in two different samples is achieved by alkylating one sample with  $d_0$ -acrylamide, and the second with its  $d_3$ -counterpart; the two samples are then combined with predetermined ratios, dialyzed, and subjected to 2D gel electrophoresis. Following visualization of the separated proteins, each spot can be excised, digested with trypsin, and examined by MALDI-TOF. The relative quantification of a number of proteins would then be obtained by comparing the relative peak heights within a reflector MALDI spectrum of two adjacent isotopic envelopes that happen to differ by  $m/z = 3$ . The application of this approach to quantitation of various proteins within the 2D map of rat serum shown in **Figure 8** is illustrated below. The map in **Figure 8**, covering the pH 3–10 IPG interval, was obtained by mixing in different proportions two fractions of rat sera, the first (30%) being alkylated with  $d_0$ -acrylamide, and the second (70%) reacted with  $d_3$ -acrylamide. A representative example of a reflector MALDI spectrum that pertains to apotransferrin is given in **Figure 9(A–C)**. The spectrum of the entire digest is given in (A), whereas (B) and (C) display two short intervals of the same spectrum and show two isotopic distributions marked A and A\* in which a difference of 3 Da in the  $m/z$  values of the corresponding peaks is clearly evident. A database search yielded the two indicated peptides, each of which contains a single cysteine. Considering the relative peak heights in both isotopic distributions, a ratio of 34:66 was obtained, which is in good agreement with the labeling ratio 30:70 prior to 2D separation.

The methodology of 2D mapping, for proteome research, has been extensively developed, it is highly reproducible and quite standardized, and surely appears to be one of the best methods still available, at present time, for analyzing very complex tissue extracts, with the ability of displaying up to 12 000 spots in large format slabs, detected by autoradiography, a resolution unmatched by any other separation technique. Yet, on the horizon, seems to be rising the star of multidimensional (as pompously

called, in reality two-dimensional) chromatography, coupling, e.g., a strong cation exchanger with a RP-LC (reversed phase, liquid chromatography). With a proviso, though: most 2D chromatography approaches do not analyze the intact proteome (as 2D electrophoresis does) but a tryptic digest of the solubilized protein. This enormously increases the sample complexity, e.g., up to half a million peptides from a mixture of 10 000 proteins, thus calling for special affinity techniques able to reduce sample complexity.

## Introduction

This chapter deals with detection and exploitation of noncovalent reversible molecular interactions during

electrophoresis. Its focus is immunoelectrophoresis and affinity electrophoresis (AE) in gels, but reference will also be made to electrophoresis in free solutions, i.e., affinity capillary electrophoresis (ACE). Crossing immunoelectrophoresis (CIE) and AE are a group of procedures in which proteins and other macromolecules are characterized by their electrophoretic migration in a gel and by their binding properties toward antibodies or other ligands.

Characteristically an interaction between an analyte and a ligand takes place during electrophoresis. The noteworthy advantage of AE is that macromolecular characterization is allowed independent of the purity of the sample and does indeed work well with small amounts of crude samples. There are even fewer requirements of the amount of the sample and ligand with capillary electrophoresis.

Gel procedures originate from the classical immunoelectrophoresis of P. Grabar, often referred to as IEA, an abbreviation for immunoelectrophoretic analysis, and from the crossing diagrams of K. Nakamura. A distinction may be made between the two-dimensional CIE of Clarke and Freeman (**Figure 1**) and the one-dimensional rocket immunoelectrophoresis of Laurell, often referred to as electroimmunoassay (EIA). Numerous technical modifications of these methods have been devised in order to obtain a certain characterization of one or more proteins. The methods are suitable for establishing an inventory of proteins and for molecular characterization of

proteins and other macromolecules. Electrophoretic methods have been developed successfully as analytical methods; the preparative aspects of electrophoresis are still waiting to be explored and generally exploited, except for a few specific applications. The principal advantages of ACE compared with gel techniques are the even smaller quantity of sample and ligand and the speed of analysis.

## Principles

Interaction during electrophoresis between an analyte and antibodies or other ligands, macromolecular or otherwise, has proven advantageous from an analytical and quantitative viewpoint. Methods have primarily been developed as gel methods for the characterization of proteins and have been expanded to other substances that migrate in an electric field and can react with a ligand, e.g., migration shift assay or charge shift electrophoresis of nucleic acid fragments.

Thus these methods contain an element of biological variation. Immunoelectrophoretic methods contain the greatest element of irreproducibility as they need antibodies as an integral part of the analytical system. Therefore results may vary enormously from one batch of antibodies to the next, and results should be interpreted with caution. The antibodies are generally polyclonal, either monospecific or polyspecific. Monoclonal antibodies may be used, depending on the purpose of the analysis. Especially

**Figure 1** CIE of serum proteins. The patterns indicate the level to which it is possible to number, identify, and characterize proteins in crude mixtures of proteins with commercial antibodies (left) and with self-prepared antibodies (right). Each curved line is a protein precipitated with its specific antibody. From left to right the major proteins are Immunoglobulin A and IgG (partly fused precipitates), complement C3, transferrin,  $\alpha_2$ -macroglobulin, albumin,  $\alpha_1$ -antitrypsin, orosomucoid (AGP), and prealbumin. The patterns also indicate the experimental variation of two-dimensional quantitative immunoelectrophoresis. (Left) Normal human serum (2  $\mu$ l) was electrophoresed for 1 h at  $10 \text{ V cm}^{-1}$  in the first dimension. Into the second dimension gel was added 0.5 ml antibodies against human serum proteins (DAKO-Cytomation). Electrophoresis was performed overnight at  $2 \text{ V cm}^{-1}$ . Agarose gel on a  $7 \times 10 \text{ cm}$  glass plate and stained with Coomassie Brilliant Blue. (Right) Normal mouse serum, amounts and conditions as above except that antibodies against mouse serum produced by us were used. Agarose gel on a  $5 \times 7 \text{ cm}$  glass plate.

in immunoblotting techniques, monoclonal antibodies are applied for specific identification of a protein and after a primary one- or two-dimensional electrophoretic separation.

In classical IEA *ad modum* Grabar, proteins are separated through zone electrophoresis in an agar or agarose gel and subsequently diffuse toward polyclonal antibodies, resulting in complex formation between protein and antibodies, which leads to precipitation in a macromolecular network of protein and antibodies. Macroscopically, precipitation lines are formed individually for each protein with their corresponding antibodies.

CIE (Figure 1) is analogous to classic IEA apart from the second step, where electrophoresis into an antibody-containing gel substitutes for the diffusion step, giving a greatly increased separation. This method allows detection and characterization of individual proteins as well as quantification. Rocket immunoelectrophoresis (EIA) is a one-dimensional electrophoresis of an antigen into an antibody-containing gel; this method is now substituted by enzyme-linked immunosorbent assay (ELISA) and other automated methods for quantification of specific antigens.

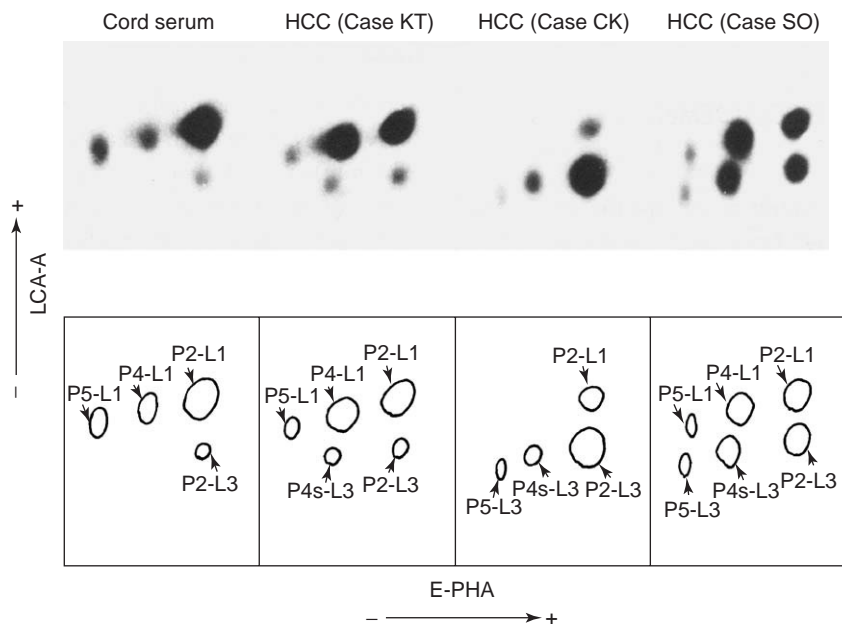

For molecular characterization of macromolecules, gel electrophoresis, especially some of the variants of the basic methods, may be used with great advantage. Without prior purification molecular

characteristics may be investigated and molecular variants like specific glycoforms may be quantified.

A biospecific interaction between two macromolecules or between one macromolecule and a smaller ligand may be exploited in AE (Figure 2). Molecular interaction takes place during electrophoresis and results in a state of dynamic complexation, resulting in the formation of one or more complexes with electrophoretic properties different from that of the uncomplexed macromolecule, leading to a change in the banding pattern. Generally the resulting band pattern is dependent on the character and amount of ligand used. The ligand may be immobilized in the gel matrix or may be present in free solution. A ligand in free solution is often preferred because the electrophoretic system will be less disturbed. Exploiting the variation in ligand concentration, kinetic binding constants may be measured, leading to a thermodynamic description of the interacting molecules.

## Immunoelectrophoresis

The ease with which individual proteins may be assessed and quantified using immunoelectrophoretic methods has resulted in widespread use of these methods when there is a requirement for specific assessment of a protein. This has been seen especially in clinical chemistry, where numerous measurements of

**Figure 2** AE shows the microheterogeneity of a glycoprotein. Glycoform identification and semi-quantitative estimation in two-dimensional lectin AE in agarose gels;  $\alpha$ -fetoprotein (AFP) from serum of patients with hepatocellular carcinoma (HCC) compared with AFP in newborn cord serum. The first dimension was run with erythroagglutinating phytohemagglutinin (E-PHA) and the second dimension with lentil LCA (LCA-A). The separated AFP spots were detected by antibody-affinity blotting. The patterns show increased E-PHA-reactive AFP, increased LCA-A-reactive AFP, and both increased E-PHA-reactive and increased LCA-A-reactive AFP glycoforms. (Reproduced with permission from Taketa K. Okayama.)

specific disease markers are required. However, since the appearance of highly automated methods (like ELISA, radioimmunoassay (RIA), and nephelometry), immunoelectrophoresis is most often used in nonroutine settings, such as in research laboratories, the methods being rather work intensive and skill requiring. Serum and plasma proteins, as well as proteins from other body fluids, have been quantified and characterized using immunoelectrophoresis as disease markers and genetic variants for use in clinical monitoring of patient condition. An early review with many references to the relationship between individual proteins and diseases has been given by Verbruggen.

### Instrumental Requirements

Gel electrophoresis is normally carried out in thin gel layers, for immunoelectrophoresis in agarose gels, usually 1 mm thick or less. Since the molecular interaction is temperature dependent, the system is sensitive to changes in temperature. This condition imposes some restrictions on the type of equipment to be used. Equipment and procedures have been designed to maintain the native conditions of macromolecules until the biospecific interaction has taken place.

Generally a power pack capable of delivering 200–300 V and 200 mA may be used to drive several electrophoresis tanks, preferably with individually regulated outlets. The electrophoresis tank consists principally of a water-cooled surface to support the gel and buffer vessels with electrodes. The gel in which the electrophoretic separation of the analytes takes place is usually cast on a plastic film or glass plate and is placed on the cooling surface in connection with the buffer vessels through several layers of filter paper soaked in electrophoresis buffer or through agarose gel slabs on a support of dialysis film.

The temperature of the instrument is maintained at the desired level by circulating water from a thermostat. For electrophoresis at a field strength greater than  $10 \text{ V cm}^{-1}$ , the temperature of the coolant might be  $10\text{--}14^\circ\text{C}$ , depending on the humidity of the air. For a field strength below  $10 \text{ V cm}^{-1}$ , a temperature of  $16\text{--}20^\circ\text{C}$  is adequate. A variety of suitable instruments are commercially available.

Accessories for easy casting and handling of gels before and after electrophoresis as well as computerized scanning and image processing systems are available commercially.

### Reagent and Substrate Requirements

Agarose is a strong and versatile matrix for gels. Many grades are commercially available: high- and

**Table 1** Some selected examples of applications of AE

Enzymes	Substrates and inhibitors
Glycoproteins	Lectins
Membrane proteins	Detergents
Monoclonal antibodies	Antigens and haptens
Nucleic acid fragments	Nucleic acid-binding proteins
Polyclonal antibodies	Antigens and haptens
Proteins	Drugs
Proteins	Dyes
Receptors	Ligands

low-electroendosmosis (EEO), high- and low-melting point, high- and low-gel strength. It is most important to choose a gel with the proper EEO. For most analyses performed as crossed immunoelectrophoresis with rabbit antibodies at pH  $\sim 8.6$  a gel with EEO in an  $M_r$  interval from 0.13 to 0.18 will be suitable.

Antibodies are usually polyclonal rabbit (or goat) antibodies, either monospecific or polyspecific preparations. Numerous antibodies are available commercially, and several companies offer custom immunization. Monoclonal antibodies are not well suited to precipitation assays and are not generally used. However, antibodies from species other than rabbit and goat may be freely applied.

Immobilized ligands as well as precursor molecules activated for immobilization for binding studies are commercially available and may be applied in AE or may be prepared using the usual methods for affinity chromatography (Table 1).

### Visualization and Detection Techniques

On termination of the immunoelectrophoresis the gel may be visually inspected for the presence and pattern of bands and precipitation lines. This is best done using oblique illumination against a dark background. The plates may be photographed or scanned at this stage, but normally the detection and further evaluation take place after staining. Numerous staining procedures have been described. Digital image processing has been developed for evaluation, comparison, and storage of pattern information, and complete computer systems are commercially available.

### Crossed Radioimmuno-electrophoresis

Crossed radioimmuno-electrophoresis (CRIE) is a technique specially designed for identifications of allergens and for determination of the antigenic specificities of patients' immunoglobulin E (IgE). The proteins toward which the patients' IgE is directed may be determined by incubating the immunoprecipitated proteins in CRIE with patient serum and subsequently visualizing the reaction by adding

radiolabeled anti-IgE and performing autoradiography. This method has been used mainly for detection of patients' IgE response to individual allergenic molecules – 'allergo-prints' – and for identification of allergens in complex allergenic mixtures through performance of 'allergo-grams'. Thus it has been established that the quantitative and qualitative binding of a specific IgE to the various antigens in an allergen extract varies significantly from patient to patient. The summation of the individual patient's specific IgE binding can be correlated to the results of other diagnostic tests, i.e., histamine release and the radio-allergo-sorbent test. The CRIE analysis of a group of patients allergic to the same allergen extract revealed that the binding of IgE differs both in frequency and in strength for various allergens. Through such analyses allergens may be identified, and the results are normally given as allergo-grams, on the basis of which major allergens can be defined.

### Fused Rocket Immunelectrophoresis

This method is a modification of rocket immunelectrophoresis. Small volumes from fractions obtained in separation experiments or samples taken through a biological process are applied in a row of sample wells across the plate in an antibody-free gel, where the samples are allowed to diffuse for up to 1 h. The proteins are then electrophoresed into the antibody-containing gel. The resulting precipitation pattern of the fused proteins from the various fractions will show the fate of each protein and will be an immunological profile of each protein, either representing the elution profile from the fractionation experiment or a profile showing the appearance and disappearance during a biological process.

### Preparative Immunelectrophoresis

An interesting application of CRIE is the preparative aspect. The separation of proteins into clearly positioned and well-spaced precipitates provides an easy means of obtaining purified antigens for immunization of animals. By loading the gel maximally with a protein sample, there will be sufficient material for successful immunization.

## Affinity Electrophoresis

In AE the analyte interacts during electrophoresis with a ligand that may be either in a bound or in a soluble state. Generally the complexation of interacting molecular partners will lead to a change in the net charge-to-size ratio. Thus in free solution the complexed macromolecule will have an electrophoretic mobility different from that of the free (or

uncomplexed) macromolecule. Binding (immobilization) of the ligand to the gel (polyacrylamide or agarose) is used when the ligand is a small molecule or is without a noteworthy electric charge. During electrophoresis the immobilized ligand will slow down the net migration of the interacting macromolecule.

A small soluble ligand with a high negative or positive charge is called an affinophore. Either by using an affinophore directly or by coupling the ligand to an affinophore it is possible to design a soluble system that is well suited for the separation in question, be it analytical or preparative. A prerequisite for using a soluble system is that the mobility of the ligand is different from that of the affinant. As the process of immobilizing a ligand may alter the binding characteristics of the ligand and may make the precise determination of total ligand concentration difficult, most often systems using soluble ligands are required for relevant kinetic determinations.

Crossed affinity immunelectrophoresis (CAIE) is very useful for identification, characterization, and quantification of isoforms and glycoforms. CAIE generally combines analysis of crude protein mixtures with ligand binding and immunological characterization. Thus the binding of a ligand to more than one macromolecule can be studied simultaneously specifically interacting macromolecules in complex mixtures can be separated and identified from those that are nonreacting. Isoforms of the same protein will react slightly differently with the ligand.

With a free unmodified ligand the binding takes place under native conditions, and the interaction is revealed with high sensitivity by changes in position as well as band characteristics. Since electroimmunoprecipitation methods are quantitative, each isoform or glycoform may be quantified directly from a crude molecular mixture.

### Glycoforms

The microheterogeneity of glycoproteins has been strikingly visualized and the amounts of individual glycoforms have been quantified using affinity immunelectrophoresis and AE in polyacrylamide gels. In human serum, some proteins, among others orosomucoid ( $\alpha_1$ -acid glycoprotein (AGP)) and  $\alpha_1$ -antitrypsin, with free concanavalin A (con A, a mannose-binding lectin) in the first dimension have shown up as several glycoforms. The glycoform pattern has revealed that the microheterogeneity of human serum glycoproteins in general is remarkably constant and is probably a general characteristic of serum glycoproteins. These studies show that the carbohydrate side-chain structures in a specific

glycoprotein vary systematically, disfavoring the original 'gadget' concept, in which a presumed sloppiness of glycosylation reactions was postulated to give rise to a statistical microheterogeneity. The microheterogeneity of AGP has been most widely studied in relation to various pathological conditions and pregnancy. In CAIE it results in the separation of this protein into three subfractions interacting differentially with con A.

Microheterogeneous glycoproteins investigated using AE include  $\alpha_1$ -fetoprotein (two glycoforms with con A) and fetal malformations,  $\alpha_1$ -antichymotrypsin and testicular and colorectal cancer,  $\alpha_1$ -fetoprotein and cancer (Figure 2), and transferrin and alcoholism.

The reproducible patterns found for serum glycoproteins has prompted the comparison of glycoform profiles between normal serum and patients' serum. This has been investigated especially with the lectins con A and LCA (lens culinaris agglutinin). The reproducibility of the glycoform pattern may indicate that glycoform variation is a part of the normal function of a glycoprotein and may be involved in the expression of the biological or biochemical function of the protein.

### Binding Constant Calculations

Apparent binding constants of ligand–affinant complexes may be calculated from the change in electrophoretic mobilities seen upon electrophoresis of an analyte in the presence of varying concentrations of ligand. The theory for calculation of binding constants was developed for AE with an immobilized ligand; the simple affinity equation for an immobile ligand is

$$1/R_{mi} = (1/R_{m0})(1 + (c/K_d))$$

where  $R_{mi}$  is the relative migration distance of a component in the presence of immobile (e.g., immobilized) ligand in the gel,  $R_{m0}$  is the relative migration distance of the uncomplexed component (i.e., the distance migrated in a gel without ligand under corresponding electrophoretic conditions),  $c$  is the total concentration of ligand (expressed in molarity of binding sites), and  $K_d$  is the apparent dissociation constant. In this equation, it is presumed that the mobility of the ligand–affinant complex is zero, that  $c$  is much higher than the concentration of the affinant, that  $K_d$  is unaffected by the electrophoresis, that the ligand is distributed randomly in the electrophoresis gel and is 100% accessible, and that the electrophoresis medium is without influence on the electrophoretic mobility of the ligand–affinant complex. By measurement of the migration distances

(relative to an internal marker) at varying ligand concentrations during electrophoresis, the apparent dissociation constant can be found by plotting  $1/R_{mi}$  as a function of  $c$ . Then the intercept on the abscissa is  $-K_d$ .

As immobile ligands may give rise to practical problems, a general affinity equation has been derived that holds for ligands with nonzero mobility:

$$(R_{m0} - R_{mi})^{-1} = (R_{m0} - R_{mc})^{-1}(1 + K_d c^{-1})$$

where  $R_{mc}$  is the migration distance of the complex relative to a nonreacting internal marker (other symbols as above) and where, again,  $c$  is presumed to be much higher than the concentration of the affinant.  $R_{mc}$  may be called the 'eigenmobility' of the complex. Here a plot of  $(R_{m0} - R_{mi})^{-1}$  as a function of  $c^{-1}$  yields a straight line intercepting the abscissa at  $-(K_d)^{-1}$  and the ordinate axis at  $(R_{m0} - R_{mc})^{-1}$ . For most lectins and glycoproteins,  $R_{mc} < R_{m0}$  as the electrophoretic mobility of the lectin at pH > 7 is most often less than that of the glycoprotein. The only other requirement of this equation is that the electrophoretic mobility of the complex should be different from that of the uncomplexed affinant; the accuracy of this method obviously increases the greater this difference is. The original simple equation derives from the general equation by setting  $R_{mc} = 0$ .

These plots allow both  $K_d$  and  $R_{mc}$  to be calculated for a given affinant–ligand system. The latter parameter may in fact give an indication of the relative number of ligands bound per molecule of affinant; the more ligand molecules bound, the smaller  $R_{mc}$  and the smaller  $(R_{m0} - R_{mc})^{-1}$ , provided that  $R_{lectin} < R_{glycoprotein}$ . This is most helpful when elucidating the structural basis for the microheterogeneity of glycoproteins. The practical range of binding constants that can be determined this way is  $10^{10} \text{ mol}^{-1}$ . For the practical calculation of lectin–glycoprotein binding constants using this method, it is obviously pivotal that the values for  $c$ ,  $R_{m0}$ , and  $R_{mi}$  be known with the highest possible accuracy. Using these equations, binding constants have been estimated for binding of soluble glycoproteins to lectins, membrane glycoproteins to lectins, monoclonal antibodies to antigens, and enzymes to substrates and inhibitors.

### Affinity Capillary Electrophoresis

In affinity capillary electrophoresis (ACE) the interaction between the molecular components usually takes place in free solution. The impressive selectivity offered by CE has been further increased by affinity applications, including pharmaceutical compounds,

DNA-binding proteins, lectins, lipids, carbohydrates, and estimation of binding constants and weak interactions.

## Introduction

The advent of sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE), with its high resolving power, was a landmark event in basic research methodology. Its full potential was, however, realized only with the advent of another procedure called protein blotting or Western blotting. This technique facilitated the transfer of proteins, separated in a gel matrix, to an adsorbent membrane for subsequent immunodetection; thus becoming a powerful tool for detecting and characterizing a multitude of proteins, especially those proteins that are of low abundance. The term 'Western blotting' was coined in an effort to retain the 'geographic' naming tradition initiated for DNA (Southern blotting) and RNA (Northern blotting) transfer. The blotted proteins formed an exact replica of the gel and became

the starting step for a variety of experiments. The subsequent employment of antibody probes directed against the nitrocellulose bound proteins has revolutionized the field of immunology. Since its inception, protein blotting has been evolving constantly, and now the scientific community is confronted with a plethora of ways and means of transferring proteins.

## Efficiency of Protein Blotting

Successful transfer of proteins from the gel to a solid membrane support depends greatly on the nature of the gel, the molecular mass of the proteins being transferred, and the membrane used. Running the softest gel, in terms of the acrylamide and cross-linker that yields the required resolution, is the best option. Transfer becomes faster and more complete with the use of thinner gels. Use of ultrathin gels, however, may cause handling problems, and a 0.4 mm thickness represents the lower practical limit. Proteins with a high molecular mass blot poorly following SDS PAGE, which results in low levels of detection on immunoblots. However, the efficiency

DNA-binding proteins, lectins, lipids, carbohydrates, and estimation of binding constants and weak interactions.

## Blotting Techniques

## Introduction

The advent of sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE), with its high resolving power, was a landmark event in basic research methodology. Its full potential was, however, realized only with the advent of another procedure called protein blotting or Western blotting. This technique facilitated the transfer of proteins, separated in a gel matrix, to an adsorbent membrane for subsequent immunodetection; thus becoming a powerful tool for detecting and characterizing a multitude of proteins, especially those proteins that are of low abundance. The term 'Western blotting' was coined in an effort to retain the 'geographic' naming tradition initiated for DNA (Southern blotting) and RNA (Northern blotting) transfer. The blotted proteins formed an exact replica of the gel and became

the starting step for a variety of experiments. The subsequent employment of antibody probes directed against the nitrocellulose bound proteins has revolutionized the field of immunology. Since its inception, protein blotting has been evolving constantly, and now the scientific community is confronted with a plethora of ways and means of transferring proteins.

## Efficiency of Protein Blotting

Successful transfer of proteins from the gel to a solid membrane support depends greatly on the nature of the gel, the molecular mass of the proteins being transferred, and the membrane used. Running the softest gel, in terms of the acrylamide and cross-linker that yields the required resolution, is the best option. Transfer becomes faster and more complete with the use of thinner gels. Use of ultrathin gels, however, may cause handling problems, and a 0.4 mm thickness represents the lower practical limit. Proteins with a high molecular mass blot poorly following SDS PAGE, which results in low levels of detection on immunoblots. However, the efficiency

of transfer of such proteins from a gel matrix has been facilitated using heat, special buffers, and partial proteolytic digestion of the proteins prior to the transfer.

Nitrocellulose, poly(vinylidene difluoride) (PVDF), activated paper, and activated nylon have all been used successfully to bind transferred proteins. The most commonly used membrane support, nitrocellulose, is disadvantageous due to the fact that the proteins are not covalently bound and nitrocellulose is brittle when dry. Small proteins tend to move through nitrocellulose membranes, and only a small fraction of the total amount actually binds. This can be obviated by using membranes with smaller pores. Some investigators have used gelatin-coated nitrocellulose for quantitative retention. In supported nitrocellulose (e.g., Hybond-C Extra), the mechanical strength of the membrane has been shown to be improved by incorporating a polyester support web, thereby making handling easier.

PVDF membranes offer the advantages of high protein binding capacity, physical strength, and chemical stability. One of the advantages of electroblotting proteins onto PVDF membranes is that replicate lanes from a single gel can be used for various purposes such as N-terminal sequencing and proteolysis/peptide separation/internal sequencing, along with Western analysis. In addition, while nitrocellulose membranes cannot be stained with Coomassie Brilliant Blue (CBB), PVDF membranes are amenable to staining with CBB, thus allowing excision of proteins for N-terminal sequencing.

Activated paper (diazo groups) binds proteins covalently but finds its main drawback in that the coupling method is incompatible with many gel electrophoresis systems. Linkage is through primary amines, and therefore systems that use gel buffers without free amino groups must be used with this paper. In addition, the paper is expensive and the reactive groups have a limited half-life once the paper is activated. Nylon has excellent mechanical strength but can only bind a small amount of protein and is not suitable for most applications. Some of

these problems are solved by using activated nylon (positively charged), which however, produces higher nonspecific binding. On account of all these problems, nitrocellulose membranes have remained the best compromise for most situations.

## Methods of Transferring Proteins from Gel to Membrane

Transfer of proteins from native or SDS-PAGE gels to nitrocellulose or PVDF membranes has been achieved in three different ways: (1) simple diffusion; (2) vacuum-assisted solvent flow; and (3) 'Western' blotting or electrophoretic elution.

### Simple Diffusion

Diffusion blotting was originally developed as a means of transferring proteins separated by isoelectric focusing on thin gels to membranes and then later expanded to other gel systems. This procedure requires placing a membrane on the surface of the gel with a stack of dry filter paper on top of the membrane. A glass plate and a weighty object are usually placed on this assembly to facilitate the diffusion process. However, this protocol had not gained widespread acceptance owing to the fact that there was no quantitative transfer of protein. Since the recent demonstration that multiple immunoblots can be generated after nonelectrophoretic bidirectional transfer of a single SDS PAGE gel with multiple antigens, there is considerable interest in diffusion mediated transfer of proteins. This protocol involves incubating the membrane on either side of a gel at 37°C for 2, 4, or 10 h (**Figure 1**). Twelve blots can be obtained using this procedure. Lifts from SDS PAGE gels for immunoblotting using this method are particularly useful in identification of proteins by mass spectrometry. Following diffusion blotting the gel can be stained with CBB. The antigens on the blot are detected by immunostaining, and the immunoblotted target band can be compared with the

**Figure 1** Nonelectrophoretic bidirectional transfer of proteins from SDS PAGE gels to nitrocellulose membranes to obtain up to 12 blots. The PAGE gel is sandwiched between two membranes, filter paper, and glass plates and incubated at 37°C for varying periods to obtain up to 12 blots.

Coomassie stained gel by superimposing the blot and the stained gel, allowing the identification of the band to be excised for tryptic digestion for subsequent mass spectrometric analysis. The greatest advantage of diffusion blotting compared with electroblotting is that several transfers or imprints can be obtained from the same gel and different antisera can be tested on identical imprints.

Quantitative information regarding protein transfer during diffusion blotting was obtained using  $^{14}\text{C}$  labeled proteins. A 3 min diffusion blotting was shown to give a transfer of 10% compared with electroblotting. Diffusion blotting of the same gels carried out multiple times for prolonged periods at 37°C causes the gel to shrink. This can be overcome by using gels cast on plastic supports.

Zymography, or activity gel electrophoresis, has also been studied regarding the utility of diffusion. Zymography involves electrophoresis of enzymes (either nucleases or proteases) through discontinuous polyacrylamide gels (PAGEs) containing an enzyme substrate (either type III gelatin or B-casein). After electrophoresis, the enzyme is renatured by removal of sodium dodecyl sulfate (SDS) and the substrate gets degraded. Staining of the gel with CBB allows the bands of enzyme activity to be detected as clear bands of lyses against a blue background. In this procedure an additional immunoblotting analysis using another gel is often required for examining a particular band that is involved. However, diffusion blotting can be used to circumvent the use of a second gel for this purpose. The activity gel can be blotted onto PVDF for immunostaining and the remaining gel after blotting can be used for routine 'activity staining'. Because the blot and the activity staining are derived from the same gel, the signal localization in the gel and the replica can be easily aligned for comparison.

### Vacuum Blotting

This is a simple blotting method developed as an alternative to diffusion blotting and electroblotting. The suction power of a pump connected to a slab gel dryer system was used to drive the separated polypeptides from the gel to the nitrocellulose membrane. Proteins with both high and low molecular mass could be transferred using membranes with an appropriate pore size.

There is the possibility of the gel drying if the procedure is carried out over longer periods (>45 min), and enough buffer should be used in such cases. In some cases, low concentration PAGEs stuck to the membrane after the transfer. The authors suggest rehydrating these gels, which makes it

swollen, and the nitrocellulose membrane can be easily detached from the gel remnants.

### Electroblotting

Electroblotting is the most commonly used method of transferring proteins from a gel to a membrane. The principal advantages are the speed and the completeness of transfer compared with diffusion or vacuum blotting. Electroelution can be achieved either by (1) complete immersion of a gel-membrane sandwich in a buffer (wet transfer) or (2) placing the gel-membrane sandwich between absorbent paper soaked in transfer buffer (semi-dry transfer).

**Wet transfer** For the wet transfer, the sandwich is placed in a buffer tank with platinum wire electrodes (Figure 2). There are a large number of different apparatuses that will efficiently transfer proteins (or other macromolecules) transversely from gel to membrane. Most of these have vertical stainless steel/platinum electrodes in a large tank (Figure 2).

**'Semi-dry' transfer** For the semi-dry transfer, the gel-membrane sandwich is placed between carbon plate electrodes. Semi-dry or horizontal blotting uses two plate electrodes (stainless steel or graphite/carbon) for a uniform electrical field over a short distance, and sandwiches between these of up to six gel/membrane/filter paper assemblies, all well soaked in transfer buffer. The assembly is clamped or otherwise secured on its side and electrophoretic transfer effected in this position, using as transfer buffer only the liquid contained in the gel and filter papers or other pads in the assembly.

There are a number of advantages to this procedure over the conventional upright protocol. Several gels can be blotted simultaneously; electrodes can be cheap carbon blocks; less power is required for transfer (and therefore a simpler power pack).

### Modifications of Electroblotting

Several variations of the basic electroblotting procedure have been developed. Among these are a number of attempts to improve the original protocol, focusing on increasing the amount of protein transferred and retained on the membrane.

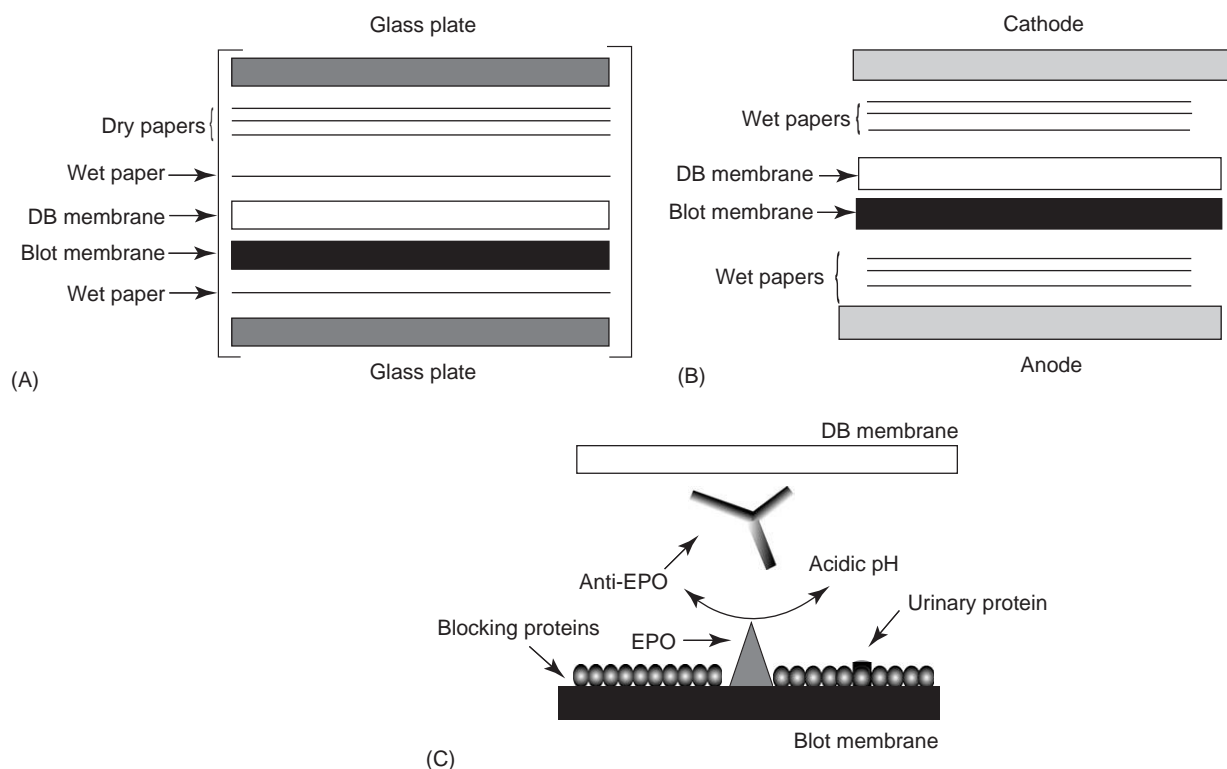

**Double blotting** This procedure was developed to reduce false positives arising as a consequence of nonspecific binding of secondary antibodies. In this protocol the membranes obtained after dot blotting or electroblotting were blocked with nonfat milk as usual, incubated with a primary antibody and washed following conventional procedures. The

**Figure 2** Western blot transfer sandwich assembly for wet transfer (top) and the preparation for transfer using the Mini-Trans-blot apparatus (bottom). The transfer membrane is sandwiched between the gel, filter papers, and support pad, with the transfer membrane facing the anode. The cassette containing the assembled gel-membrane sandwich is inserted into the Trans-blot apparatus containing cold transfer buffer, and the electro-transfer carried out. (Adapted from Bio-Rad Instruction manual.)

principle of double blotting (DB) was to transfer the primary antibody separately from the blot membrane to a new support called the DB membrane (**Figure 3**). Two variants of the DB were developed successfully, (1) pressure DB (**Figure 3A**), which does not use electrophoresis (only simple diffusion) and (2) electro DB, which involves electrophoresis (**Figure 3B**).

**Pressure DB** In this procedure a second PVDF membrane (DB membrane) was cut to the dimensions of the dot-blot membrane and moistened with methanol and  $0.1 \text{ mol l}^{-1}$  glycine/HCl pH 2.5. This membrane was layered on a 3-mm filter paper sheet moistened with the same buffer and laid on three dry filter paper sheets. The blot membrane was placed

**Figure 3** Double blotting (DB). (A) Experimental setup for pressure double blotting, a nonelectrophoretic transfer procedure. The blot membrane was sandwiched between a second PVDF membrane (DB) membrane cut to the dimensions of the blot membrane and filter papers as shown in the assembly. The assembly was clamped between two glass plates, and contact was maintained for 5 min before processing the DB membrane further. (B) Experimental setup for electro DB. The DB membrane was incubated in a 0.7% (v/v) (pH 2.79) acetic acid solution and layered onto the blot membrane between two stacks of filter paper wetted with the same solution. The assembly was placed in a semi-dry electrophoretic blotting instrument with the blot membrane and DB membrane facing the anode and the cathode, respectively, and transferred for 10 min. (C) The principle of DB. The blotting membrane with erythropoietin (EPO) and other urinary proteins was blocked with 5% nonfat milk. The acidic pH of the DB membrane and filter papers induce the dissociation of the primary antibody (anti-EPO), which is transferred to the DB membrane. (Reprinted with permission from Lasne F (2001) Double-blotting: A solution to the problem of non-specific binding of secondary antibodies in immunoblotting procedures. *Journal of Immunological Methods* 253: 125–131; © Elsevier.)

onto the DB membrane and covered with a filter paper sheet wetted with the same buffer. This assembly was placed between two glass plates and secured by clamps as shown in **Figure 3A**, and this contact was maintained for 5 min. Use of pressure results in the capture of the desorbed antibody by the capture DB membrane facing the membrane with the antigen and primary antibody. The decreased pH of the buffer used, a classical desorption method in immunoaffinity chromatography, induces dissociation of the primary antibody from the blotted antigen. Due to the acidic pH, the primary antibody, having a pI much higher than the pH of the acetic acid solution, is positively charged and migrates towards the DB membrane that is in contact with the cathode. Since the acidity does not affect hydrophobicity with PVDF, the antigen and the interfering proteins are retained on the blot membrane.

**Electro DB** This protocol was found to be efficient with electroblotted membranes. The DB membrane was conditioned in a 0.7% (v/v) (pH 2.79) acetic acid solution. It was then layered onto the blot membrane between two stacks of filter paper moistened with the same solution in the semi-dry electrophoretic blotting instrument with the blot membrane and the DB membrane facing the anode and the cathode, respectively (**Figure 3B**). A constant current of  $0.8 \text{ mA cm}^{-2}$  was applied for 10 min. Here again, the low pH used helps in desorption of the primary antibody from the antigen. The application of current thus helped to drive the primary antibody from the primary membrane to the capture membrane. The primary antibody was thus desorbed from its corresponding antigen and transferred onto the DB membrane (**Figure 3C**). The membranes were then disentangled, and the DB membrane was

blocked and further incubated with secondary antibody and developed according to a standard method.

**Slice blotting** This is a simple method of blotting that can map the *in vitro* release of cytokines, growth factors, chemoattractants, chemorepellents, morphogens, enzymes, and other paracrine signals in spatially organized systems, such as brain tissue, under a variety of stimuli and conditions. In this protocol, a brain slice is placed onto a transfer membrane (nitrocellulose) that can trap signal molecules, such as neurotransmitters, proteins, and peptides. Once they are released, molecules diffuse to the nitrocellulose membrane, where they are bound and immobilized. The membrane will accumulate the secreted substances over time, in a pattern reflecting the distribution of active release sites within the slice, and the standard Western blotting techniques can be used to develop this picture.

**Tissue printing (pressure)** This procedure allows the transfer of proteins to nitrocellulose membranes when a fresh cut organ or the cross sections of seeds, stems, tubers, leaves, and fruits are pressed against the membrane surface. This procedure was further modified to detect plant virus coat proteins on whole leaf blots. In this procedure, plant leaves to be blotted were placed on dry nitrocellulose membrane. The leaf and the nitrocellulose membrane were sandwiched on either side with blotting paper or one 0.75 inch thick block of plywood. The sandwich was positioned into a Carver laboratory press, and 10 000 psi of pressure was applied for 2 min. After disassembly, the membrane was air-dried for 20 min prior to standard immunodetection procedures. This procedure was shown to transfer protein uniformly. Some amount of chlorophyll was found to be transferred along with the protein, but this was not found to interfere significantly with the subsequent visualization of results.

**Native electrophoresis and Western blot analysis** Under native PAGE electrophoresis conditions, proteins retain their higher-order structure and often retain their biological activity. SDS, dithiothreitol or  $\beta$ -mercaptoethanol, and heat are omitted from the standard Laemmli SDS protocol. Many factors, including size, shape, and native charge determine the migration of proteins. The resolution of non-denaturing electrophoresis is generally not as high as that of SDS PAGE, but the technique is useful when the native structure or enzymatic activity of a protein must be assayed following electrophoresis.

**Grid immunoblotting** Grid immunoblotting is a procedure that allows the simultaneous testing of up to 20 different samples for specific antibodies against up to 20 different antigens or allergens in a single nitrocellulose membrane sheet. Only  $\sim 150$ – $200\ \mu\text{l}$  of total sample volume is required for the assay, compared with 10 times more than is required by standard enzyme-linked immunosorbent assay (ELISA). This method is especially useful when the sample volume is the limiting factor especially in cases where blood has to be drawn from allergic children to be tested against various allergens.

Grid immunoblotting consists of three basic steps. First, the proteins are immobilized on the carrier membrane. For this, cyanogen bromide activated (to improve protein binding) nitrocellulose membrane is placed onto a multichanneled manifold of the Surf-blot apparatus (Idea Scientific, Minneapolis, MN). The various proteins are then applied to the channels and incubated for 1 h. After washing, the grid is disassembled and the unoccupied binding sites on the membrane are blocked. Second, the blot is incubated with primary antibody (e.g., serum or monoclonal antibody) or other specific probes such as saccharide-specific lectins; and third, the specific binding is sought with a detection system.

**Multiple antigen blot assay** This assay, termed MABA, is an adaptation of the cross-dot system and checkerboard immunoblotting. The antigens (up to 28 different antigens), such as synthetic peptides, are immobilized on a nitrocellulose membrane in 28 parallel lanes delineated by a template (Multiscreen apparatus). Strips are then excised perpendicular to the antigen lanes, individually immersed in immune sera, and developed according to standard procedures. This method allows the screening of the reactivity of a serum against 28 different antigens and was found to be twice as sensitive as conventional ELISA. In a single assay, MABA can be used to analyze qualitatively as many as 26 different sera against 28 individual antigens, the equivalent of eight ELISA plates (728 wells).

**Multiple tissue Western (MTW) blot** Human MTW blots provide a new immunological tool for the investigation of tissue-specific protein expression. These are premade immunoblots prepared using proteins isolated from adult human tissue. The proteins are isolated from whole tissue under conditions engineered to minimize proteolysis and to ensure maximal representation of tissue-specific proteins. SDS solubilized proteins are fractionated by SDS PAGE and electroblotted onto PVDF membranes to generate blots ready for incubation with

specific antibodies. Several specific antigens can be detected in separate cycles of antibody incubations using the same MTW blot. This approach was possible using a stripping procedure that allowed selective removal of both primary and secondary antibodies in a single incubation. The use of multiple reprobing makes this a very useful tool for studying human tissue-specific proteins.

**Dot-immunobinding assay (Dot-Iba)** This procedure entails placing the antigen on the surface of nitrocellulose cellulose membrane (NCM) disks (1 cm diameter) and incubating at 4°C for 12 h. The disks were developed using a standard procedure, and a positive reaction was indicated by the development of an insoluble purple color in the central portion of the NCM disks. In contrast to conventional bacteriological methods, Dot-Iba required only 6 h to be performed in the laboratory. This has been used to measure mycobacterial antigens in cerebrospinal fluid (CSF) specimens for laboratory diagnosis of tuberculous meningitis with a sensitivity level of 100 ng of antigen per milliliter. NCM disks containing the 14 kDa (100 ng ml<sup>-1</sup>) mycobacterial antigen were used as a positive control.

**High-efficiency blotting of high-molecular mass proteins** Prolonged electrotransfer (16–21 h) at a high current density coupled with inclusion of SDS in the transfer buffer, to enhance protein elution, has been used to transfer proteins efficiently with a high molecular mass. Special blotting buffers (40 mol l<sup>-1</sup> Tris, 20 mol l<sup>-1</sup> sodium acetate, 2 mol l<sup>-1</sup> ethylene diamine tetraacetic acid, pH 7.4, 20% (v/v) methanol, 0.05% (v/v) SDS), novel gels (50:1 ratio of acrylamide: bisacrylamide), composite agarose-PAGEs containing SDS and urea, a heated transfer buffer (without methanol), or partial proteolytic digestion of high-molecular-weight proteins prior to transfer have also been used for this same purpose.

**Western blot with kits** The KODAK BIOMAX multiblot kit for proteins applies the ease and convenience of Western blotting to a multiplex format. The proteins are transferred, after electrophoresis, with a conventional transfer apparatus from the gel to the BIOMAX multiblot kit's proprietary membrane stack using a specially formulated transfer buffer (Figure 4). Because the membrane has high affinity protein binding and a low capacity, proteins can be transferred from a single gel onto the BIOMAX multiblot kit's membrane stack, producing up to 10 blots. Experiments have demonstrated that at least a 50-fold difference

**Figure 4** The KODAK BIOMAX multiblot kit for transfer of proteins. The membrane has a high affinity protein binding and low capacity. The proteins are transferred from a single gel onto the BIOMAX multiblot kit's proprietary membrane stack, producing up to 10 blots.

(10–500 ng of protein could be detected) in amount of protein can be measured on all 10 blots.

**Blotting of stained proteins from PAGE gels to transparencies** CBB stained proteins were transferred nonelectrophoretically from PAGE gels to transparencies similar to those used in plain or regular photocopiers. Proteins are first separated by regular SDS PAGE, stained with CBB, and destained. The destained gel is pressed against the transparency for 2 h at room temperature or for 30 min at 40°C. The blue bands corresponding to the protein-dye complexes are transferred to the transparency. Since the transparencies are poreless and hence not conductive in an electric field, it is not possible to blot dye-protein complexes electrophoretically from PAGE gels to transparencies. Protein patterns present in several types of gels – SDS PAGE, nondenaturing PAGE, isoelectric focusing PAGE, and SDS-agarose – all were found to be transferred successfully following staining with the dye. Proteins visualized with other organic dyes such as Fast Green FCF2, Uniblue A3, and Procion Blue MX-R4 were also found to transfer, but proteins stained with Stains-all 5 or silver did not. This transfer method provides a simple, economical way of preserving data and a convenient method of displaying data using an overhead projector. The protein pattern obtained is sharper using this method of transfer, presumably due to reduced diffusion during the transfer process, and there is no change in the antigenicity of the proteins.

**Treatment of nitrocellulose blots to improve detection** A large number of proteins bind strongly to nitrocellulose under different experimental conditions. However, milk, Triton X-100, Nonidet P-40, and Tween-20 have all been shown to remove bound proteins. Milk, however, has been generally used to block unoccupied sites on the nitrocellulose membrane and thus prevent nonspecific binding. The sensitivity of nondenaturing blots can be increased by soaking the membrane in acidic buffer after transfer. In addition milk-stripping of antibody from membrane can be completely eliminated by exposure to acidic buffer.

### Antigen detection

**Antigen detection by protein stains** Proteins have been detected after immunoblotting onto membrane supports directly by use of organic dyes (Ponceau red, amido black, fast green, CBB), using fluorescent labels (fluorescamine, coumarin), various silver staining methods, and colloidal particles such as gold, silver, copper, iron, or India ink. Metal chelate stains such as the Ferrozine/ferrous (iron(II)) complex and the ferrocyanide/ferric (iron(III)) complex have been used successfully to stain one-dimensional and two-dimensional electroblots. Ferrozine and Ferene S, when combined with ferrous (iron(II)) ions, effectively stain proteins with a sensitivity comparable with amido black stain, producing purple and blue stains, respectively.

**Immunodetection of antigens** Radioactive and enzyme-linked reagents have been used for immunodetection of antigens after blotting. Radioactive methods use iodinated ( $^{125}\text{I}$ ) staphylococcal protein A or streptococcal protein G to bind to the primary antibody that is bound to the desired antigen on the membrane blot. The radiolabeled antigen can then be detected using autoradiography. Enzyme-linked reagents include secondary antibodies coupled to either horseradish peroxidase or alkaline phosphatase, which bind to antigen-antibody complexes on the membrane. Using appropriate substrates (those that produce color or light), depending upon the degree of sensitivity required, the desired protein bands on the blot can be visualized. Protein A bound gold particles that bind to the primary antibody to produce a red coloration have also been used. The biotin-streptavidin system has also been used for detecting immune complexes.

# Carbohydrates

## Introduction

Carbohydrates are a large family of vicinal polyhydroxy compounds and can be classified into mono-, oligo-, and polysaccharides.

Monosaccharides contain carbonyl groups and they are – like their deriving oligo- and polysaccharides – without charge and therefore electrically neutral. Derivatives of monosaccharides are alduronic acids, aldonic acids, and sugar phosphates having carboxyl or phosphate groups. These compounds as well as their oligomers and polymers possess electric charges and migrate in the electric field. As electrically neutral mono-, oligo-, and polysaccharides do not migrate in the electric field, they have to be transferred to charged complex compounds by reaction with inorganic polyhydroxy anions like tetrahydroxyborate, arsenite, germanate, molybdate, and vanadate. These charged complex compounds migrate in the electric field with different mobilities.

The anionic complex between carbohydrates and borate is the most studied and has been known for a long time. The borate anion exists in aqueous solution as tetrahydroxyborate with tetrahedral symmetry, and reacts with vicinal hydroxyl groups to the following charged complex compounds shown in **Figure 1**. The formation of such a charged complex can take place only when the distance between the hydroxyl groups in the organic molecules is similar to that in the borate anion, which is 2.36–2.39 Å. The strength of such borate polyol complexes

depends on the number of such –O–O– units as well as on their conformation in the resulting molecules. They have a positive correlation with their mobilities in the electric field. The same situation is valid using phenyl boric acid and diphenyl boric acid. Similarly, oligohydroxyanion–carbohydrate complexes are formed with germanate, hydrogenarsenite acid, molybdate, and vanadate. The strength of the resulting polyol complex strongly depends on the structure of the carbohydrate part.

For the practical purposes two modes of electrophoretic operations are used:

1. zone electrophoresis on a flat inert support;
2. zone electrophoresis in fused silica capillaries (length: 20–100 cm, 25–75 µm i.d.) with potentials of 10–30 kV (capillary zone electrophoresis).

## Electrophoresis of Carbohydrates on a Flat Inert Support

### Chromatographic Paper

Cellulose is the oldest support for these electrophoretic separations. The paper is soaked with the electrolyte before spotting the sample on the wet surface. A special disadvantage is the need to use high voltage in order to obtain satisfactory separation (30–100 V cm<sup>−1</sup>) with sharp zones and reduced separation time. The use of expensive equipment is necessary as intense cooling is required. A further disadvantage of paper electrophoresis is the limited possibility to visualize the separated sugar zones.

The following reagents can be used for the visualization of zones containing low molecular mass-carbohydrates:

- Alkaline silver nitrate, sodium metaperiodate-benzidine (or *o*-dianisidine) for all vicinal polyhydroxy compounds like sugars, sugar alcohols, aldonic acids, etc.
- Aniline phthalate, aniline trichloroacetate, *p*-anisidine hydrochloride, *p*-anisidine trichloroacetate, *m*-phenylenediamine, etc., for reducing sugars and uronic acids.
- Acetylacetone-*p*-dimethylaminobenzaldehyde for amino sugars (Morgan Elson reaction).

### Glass Fiber Paper

This support overcomes the limited possibilities of visualization of the separated sugar zones. It enables the use of sulfuric acid containing carbohydrate

**Figure 1** Reaction of tetrahydroxyborate with vicinal hydroxyl groups of the corresponding carbohydrate.

reagents. The mobilities of the zones are higher than when using cellulose matrices of the chromatographic paper due to their reduced adsorption. A disadvantage is the high electroendosmosis due to an enhanced charge of the glass fiber surface. This can be avoided by silanization of the surface with dichlorodimethylsilane, which leads to a decrease in mechanical stability. Separations of mono-, oligo-, and polysaccharides can be successfully carried out using this material.

### Silanized Silica Gel

This material was developed to overcome the disadvantage of the low stability of the silanized glass fiber paper. After the surface of the silanized silica gel (for thin layer chromatography) is covered with a thin film of 1-octanol, it is slurried with the electrolyte containing polyvinylpyrrolidone and is then spread on thin layer plates (20 × 20 cm) giving a weak quasigel layer. After storing for 3 h in a humid atmosphere, the sample can be spotted on these plates and electrophoresis can be carried out using a total potential of 200–400 V. This support can be used for the separation of mono- and oligosaccharides, sugar alcohols, uronic acids, sugar phosphates, and polysaccharides (Figure 2).

Silanized silica gel is stable against aggressive reagents and in addition to those reported in the section 'Chromatographic paper', the following

reagents can be preferably applied for visualization:

- Alkaline potassium permanganate for all vicinal polyhydroxy compounds (sugar, sugar alcohols, aldonic acids, alduronic acids, etc.).
- Aniline–diphenylamine phosphoric acid, orcinol–Fe(III)–sulfuric acid for mono- and oligosaccharides as well as uronic acids.
- 1,3-Dihydroxynaphthalene (naphthoresorcinol) – sulfuric acid with or without the addition of 1-octanol for mono-, oligo-, and polysaccharides.
- 1,3-Dihydroxynaphthalene–hydrochloric acid for uronic acids.

### Cellulose Acetate Membranes

This support, which is used in the field of proteins, was introduced for the separation of glycosaminoglycans (e.g., heparin, hyaluronic acid, etc.), which is important in the field of medical diagnosis (e.g., for the detection of mucopolysaccharidosis). This group of compounds contains negative and positive charged units (e.g., uronic acids, hexosamines) in different proportions. The visualization of the separated glycosaminoglycans is carried out by staining with dyes, which have strong affinities to such polysaccharides. The most frequently used ones are Alcian blue (a copper-containing phthalocyanine) and Toluidine blue. Furthermore, the separation of acid and neutral polysaccharides containing thickening agents on this support has been described in the field of food analysis. The zones of acidic polysaccharides can be visualized with basic dyes like Methylene blue, Amido black 10B, or Toluidine blue O. The neutral polysaccharides can be visualized by the reaction with Fuchsin–sulfurous acid.

### Agarose Gel

As an alternative to cellulose acetate strips, this support can be used for the separation of glycosaminoglycans. It offers the possibility to separate these compounds into two dimensions. For visualization, the glycosaminoglycans are at first fixed in the gels by Cetavlon (cetyltrimethylammonium bromide) and then stained with Toluidine blue.

### Polyacrylamide Gel

This support, which is of widespread use in the field of protein and DNA electrophoresis, is applied for the separation of oligosaccharides, labeled by fluorophores like 2-aminoacridone or 8-aminonaphthalene-1,3,6-trisulfonate, formed by enzymatic hydrolysis of glycoproteins. For this purpose small-pore gel material is used either with uniform pores or as

**Figure 2** Thin-layer electrophoresis of uronic acids on silanized silica gel, pretreated with octanol-1 in 0.07 mol l<sup>-1</sup> barium acetate solution. Electrophoresis: 400 V, 150 min, 16°C. Lanes: (1) galacturonic acid, (2) mannuronic acid, (3) glucuronic acid, (4) hydrolysate of gum arabic (glucuronic acid), (5) hydrolysate of sodium alginate (mannuronic and guluronic acids), (M) mixture of (1–3) and guluronic acid, (H) omega-hydroxymethylfurfural. Sample loading: 10 µg of each individual compound. Visualization with naphthoresorcinol–sulfuric acid. Origin indicated.

gradient gel. The visualization of the separated zones can be done by illumination under an ultraviolet lamp.

**Application** The electrophoresis on flat inert supports is used for:

- Separation of glycosaminoglycans like hyaluronic acid, heparin, chondroitin sulfate, keratan sulfate, etc., in biological materials (like urine). This method is important in the field of medical diagnosis (e.g., identification of mucopolysaccharidosis). The supports most often used for this purpose are cellulose acetate and agarose gel.
- Separation of acid and neutral polysaccharides, e.g., those of food hydrocolloids (thickening agents, e.g., guar, gum arabic, carrageen, etc.) and pectins. The best supports are silanized glass fiber paper or silanized silica gel-1-octanol.
- Mono- and oligosaccharides can be easily separated on silanized glass fiber paper and on silanized silica gel-1-octanol plates. Both systems offer, as a rapid screening method, an alternative to thin-layer chromatography especially for a clear identification of uronic acids in a mixture with neutral monosaccharides, as it occurs in the case of hydrolysates of acid

**Table 1** Some examples for the electrophoretic separation of carbohydrates on flat inert supports

<i>Carbohydrates</i>	<i>Support</i>	<i>Complexing agent; electrolyte; applied voltage</i>	<i>Detection</i>
Monosaccharides, disaccharides, methyl sugars, glycosides, cyclitols, sugar alcohols	Chromatographic paper (Whatman 3)	0.2 mol l <sup>-1</sup> Sodium tetraborate, pH 10.0; 0.05 mol l <sup>-1</sup> sodium tetraborate, pH 9.5; 500 V, 1300–1400 V	Aniline–hydrogenphthalate
Monosaccharides, disaccharides, sugar alcohols	Chromatographic paper (Whatman 4)	0.1 mol l <sup>-1</sup> Sodium arsenite, pH 9.6	Aniline–phosphates, H <sub>2</sub> O <sub>2</sub> , CrO <sub>3</sub> –H <sub>2</sub> SO <sub>4</sub>
Monosaccharides, sugar alcohols, amino sugars	Chromatographic paper (Whatman 3, Schleicher-Schüll 2043b)	Sodium molybdate (25 g per 1000 ml), pH 5.0, 1.5% sodium metavanadate, pH 8.7; 3000 V	Silver nitrate–ethanol, sodium hydroxide, <i>p</i> -anisidine–HCl; acetone–KMnO <sub>4</sub>
Mono- and disaccharides, alduronic acids, methylated sugars, polysaccharides (thickening agents)	Silanized glass fiber paper	0.05 mol l <sup>-1</sup> Sodium tetraborate, pH 9.0, 0.1 mol l <sup>-1</sup> barium acetate, 0.1 mol l <sup>-1</sup> zinc acetate, 0.1 mol l <sup>-1</sup> calcium acetate	1,3-Dihydroxynaphthalene (naphthoresorcinol)–H <sub>2</sub> SO <sub>4</sub>
Mono- and oligosaccharides, sugar alcohols, sugar acids, sugar phosphates, polysaccharides (thickening agents)	Silanized silica gel (for thin-layer chromatography)–1-octanol	0.3 mol l <sup>-1</sup> Borate buffer, pH 10.0 containing 0.02 mol l <sup>-1</sup> EDTA and 0.44% polyvinylpyrrolidone (K-90: MM: 350 000)	1,3-Dihydroxynaphthalene–H <sub>2</sub> SO <sub>4</sub> –1-octanol
Mono- and oligosaccharides, esp. those obtained from glycoproteins) labeled with fluorophores like 2-aminoacridone or 8-amino-naphthalene-1,3,6-trisulfonic acid); lipopolysaccharides	Small porous polyacrylamide gel (with or without pore gradient)	0.1 mol l <sup>-1</sup> Tris–borate/boric acid buffer, pH 8.3, 0.01 mol l <sup>-1</sup> Tris–glycine buffer (according to Laemmli), 0.1 mol l <sup>-1</sup> Tris–HCl buffer, pH 6.8 containing 2% SDS for lipopolysaccharides	UV-light 265–365 nm (UV- or fluorescence) for labeled oligosaccharides; periodic acid–silver nitrate for lipopolysaccharides
Glycosaminoglycans (hyaluronic acid, heparin, chondroitin sulfate, etc.)	Cellulose acetate membranes	0.2 mol l <sup>-1</sup> Barium acetate, pH 5.0 or pH 8.0, 0.05 mol l <sup>-1</sup> lithium chloride, 0.01 mol l <sup>-1</sup> HCl (pH 2.0). Two dimensional: 1st direction: 0.1 mol l <sup>-1</sup> pyridine, 0.47 mol l <sup>-1</sup> formic acid, pH 9.0; 2nd direction: 0.1 mol l <sup>-1</sup> barium acetate, pH 8.0	Alcian blue
Glycosaminoglycans (heparin, hyaluronic acid, chondroitin sulfate, etc.)	Agarose (0.9% agarose)	0.06 mol l <sup>-1</sup> Barbitol (5,5'-diethylbarbituric acid) buffer, pH 8.6, 0.05 mol l <sup>-1</sup> diaminopropane–acetate (pH 8.5)	Cetavlon-Alcian blue, Toluidine blue

polysaccharides such as gum arabic (Figure 2). The advantage of the silica gel-1-octanol layer is that, contrary to thin-layer chromatography, no additional preparations of the sample before the electrophoresis procedure is necessary, as it was found, for example, for the separation of lactulose and lactose in processed milk. A drop of the sample is put on the layer and the electrophoresis carried out immediately to obtain clear distinct zones for visualization.

Table 1 lists some examples for the electrophoretic separation of carbohydrates on the supports described above. Table 2 lists the electrophoretic mobilities of some common mono-, di-, oligosaccharides, sugar alcohols, and aldonic acids. Table 3 summarizes the electrophoretic mobilities of sugar acids, sugar phosphates, and amino sugars. In Table 4, the chromatographic conditions used in Tables 2 and 3 can be deduced by the use of the corresponding reference letters (A–G).

## Capillary Electrophoresis of Carbohydrates

Capillary electrophoresis (CE) is a very effective method for the separation and determination of carbohydrates. It offers higher resolution of separation, requires lesser analysis time, and can be automated. CE can be used to separate mono-, oligo-, and polysaccharides, their acid and basic derivatives as well as glyco-conjugates like glycoproteins, proteoglycans, and glycolipids. A characteristic advantage of CE is the requirement of extremely small amounts of sample as the detection limits range from pico- to attomoles depending on the derivatization conditions used. The mode of separation is almost the same as described in the first two sections, but instead of flat inert supports separations are carried out in fused silica capillaries of lengths of 20–100 cm and having an internal diameter of 25–100  $\mu\text{m}$ . One of the fundamental processes that drive CE is the

electroosmotic flow (EOF). EOF is a consequence of the surface charge on the wall of the capillary. The fused silica capillaries that are typically used for separations have ionizable silanol groups in contact with the buffer contained within the capillary. Separations can be carried out in two modes: either with the electroosmotic flow (EOF) or against it (Figure 3), Co-EOF allows the shortening of analysis time.

The detection of the separated zones in the tube can be carried out in different modes: detection of underivatized carbohydrates through direct UV detection, indirect UV detection, or by electrochemical methods. Carbohydrates with labeled chromophore groups can be detected by UV or fluorescence detectors.

### Detection of Underivatized Carbohydrates

**Direct UV detection** Generally, carbohydrates have no chromophores in their molecules and they absorb UV light only at wavelengths below 200 nm. Exceptions are acidic disaccharides obtained by the enzymatic digestion of glycosaminoglycans, which have an unsaturated uronic acid unit in their molecules. They can be detected by direct UV detection at 232 nm. The oligosaccharides containing *N*-acetylglucosamine, *N*-acetylgalactosamine, and sialic acid residues can be detected at 200 nm but at this range the UV absorbances are not selective.

As an interesting effect, a 2–50-fold increase in signal intensity for mono- and oligosaccharides using UV detection at 195 nm was observed by applying a borate buffer at pH values between 9 and 10, which enables the detection of these sugars by direct UV absorption. The highest reproducibility could be obtained at elevated temperatures (40–60°C).

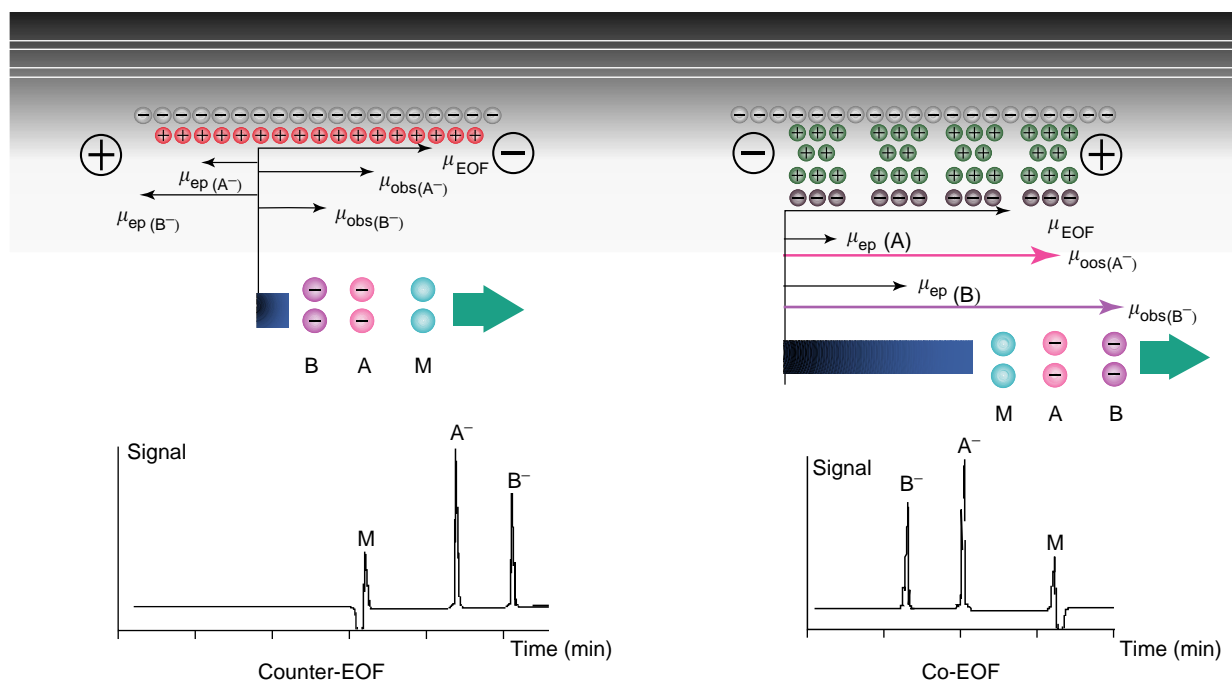

Table 5 gives some examples for the practical application of CE using direct UV detection.

**Indirect UV detection** In strong alkaline medium and in the presence of alkali-metal hydroxides (LiOH, NaOH, KOH), the carbohydrates possess slight acidic properties due to the ionization of the hydroxyl groups, yielding in the so-called alcoholates. (The ionization constants *pK* for mono- and oligosaccharides in water are between 11.98 and 12.74, and for sugar alcohols ~13.5.) Under these conditions, these compounds migrate in the electric field. When using

**Figure 3** Counter and co-electroosmotic flow of negatively charged analytes A, B, and a neutral analyte M in capillary electrophoresis.  $\mu_{\text{EOF}}$ , electroosmotic flow (EOF);  $\mu_{\text{obs}}$ , observed flow of the individual analyte;  $\mu_{\text{ep}}$ , flow of analyte without EOF.

indirect UV detection, a UV-absorbing co-ion with high molar absorbance or with high fluorescence is added to the electrolyte used to provide a constant detector response. Due to the maintenance of charge neutrality, the analyte with the same charge as the co-ion displaces the co-ion resulting in a decrease in detector response. Indirect photometric or fluorometric detection has the advantage that there is no need for pre- or postcolumn derivatization of the compounds to be studied. The following compounds are used as co-ion for the application of indirect detection: sorbic acid, tryptophan, 1-naphthylacetic acid,  $\beta$ -indoleacetic acid, 2,6-pyridinedicarboxylic acid, benzoic acid in the case of alkaline medium. For the separation of negatively charged species the following compounds are used: heparin-derived oligosaccharides in neutral or slight acidic medium (pH 2.5–3.5), 5-sulfosalicylic acid, or 1,2,4-tricarboxybenzoic acid.

For indirect fluorescence detection coumarin or fluorescein are used. This indirect UV (or fluorescence) detection of the separated carbohydrates appears simple, but it has some drawbacks such as the instability of the detection system itself resulting in a drift of the baseline, the unfavorable relation between the analyte and the co-ion giving low efficiencies at higher sample concentrations of the sample, and the lack of specificity for the detection. Nevertheless, this method was applied for the

determination of sugars in food samples such as fruit juices (Figure 4).

**Electrochemical detection** There are two variations of this technique:

1. amperometric detection at a constant potential (ADCP), and
2. pulsed amperometric detection (PAD).

*Amperometric detection at a constant potential* The materials best suited for use as working electrodes are elementary copper and copper(I) oxide. Using a microelectrode consisting of a Cu wire of 25  $\mu\text{m}$  diameter, Ag/AgCl–3 mol l<sup>-1</sup> KCl as reference electrode, and a Pt wire as an auxiliary electrode at +0.6 V, 15 different mono- and oligosaccharides were detected in a single run using a fused-silica capillary (length: 73 cm, 50  $\mu\text{m}$  i.d.) at 100 mmol l<sup>-1</sup> NaOH and 11 kV. The limit of detection was below 50 fmol and the linear response of the detector signal/concentration was over four decades. The copper electrode maintains a constant potential even after hundreds of runs. This system proved to be useful for the determination of sugars in carbonated soft drinks like Coca Cola. An alternative system using the ADCP technique is the use of copper(I) oxide (Cu<sub>2</sub>O) embedded in a matrix of conductive carbon cement with Ag/AgCl as the

reference electrode and stainless steel fiber as the auxiliary electrode.

**Pulsed amperometric detection** The principle of this technique is based on the electrochemical oxidation of the carbohydrates at surfaces of noble metal microelectrodes such as gold or platinum but the surfaces of these electrodes strongly adsorb the oxidation products resulting in a rapid decrease in analyte response. For cleaning the surfaces of these electrodes by oxidation, the positive potential is enhanced yielding a layer of oxides of the noble metal, which are then immediately reduced by changing the potential to negative values. When using a gold working electrode the range of the voltage waves are as follows: (1) detection step, 200–300 mV (110–220 ms); (2) 900–1200 mV (55–110 ms) for the cleaning step (oxidation); and (3) 500–1000 mV (110–330 ms) for restoring the electrodes (reduction step). Using  $0.1 \text{ mol l}^{-1}$  NaOH as an electrolyte and a voltage of 30 kV the common sugar and sugar alcohols can be separated with this system. This method has proved to be useful for the determination of glucose in human blood and for the analysis of oligosaccharide residues resulting from glycoproteins and glycopeptides. A drawback of PAD is the necessity of special pulse sequences requiring expensive instrumentation.

**Mass spectrometry (MS) detection** In the case of MS detection, there must be a distinction between online and offline CE–MS modes.

In the online mode the fused silica capillary used in CE is connected to the mass spectrometer through an electrospray ionization interface. This system is used for the identification of oligosaccharides, released by enzymatic digestion of glycosaminoglycans (e.g. heparin), glycopeptides, and glycoproteins. The offline mode is used for the identification of the structure of glycopeptides. Data are collected by a micropreparative CE system for the mass determination by matrix-assisted laser desorption ionization mass spectrometry.

**Refractive index detection** A microvolume refractive index detection method has been developed for CE consisting of a micro-interferometer back-setter system, illuminated by a He–Ne laser giving a characteristic interference pattern. The change of such a pattern is due to the change of the refractive index caused by the separated substance. This detection system was tested for the separation of mono- and oligosaccharides.

### Detection of Derivatized Carbohydrates (Precolumn Derivatization)

Labeling of carbohydrates by the introduction of a chromophore or a fluorophore group leads to a fundamental improvement of detection of the separated carbohydrate zones after the electrophoretic run. For this purpose the following chemical reactions are used:

1. Reductive amination: reaction of the reducing carbohydrate with primary aromatic or heterocyclic amines in the presence of sodium cyanoborohydride yielding the corresponding aminoalditols, e.g.,

2. Condensation of the reducing carbohydrate with 1-phenyl-3-methyl-5-pyrazolone (PMP) in alkaline medium yielding the corresponding bis-PMP-compound:

3. Condensation of reducing sugars with aromatic amines yielding the corresponding hydrazones, in reaction [III], and

4. Condensation of carboxylated carbohydrates with UV-absorbing amines in the presence of carbodiimide:

The reductive amination (reaction [I]) is the most frequently used labeling reaction. Regarding the chromophore (respectively) fluorophore group there must be distinction between (1) neutral or ionizable and (2) permanently charged derivatives. In Table 6, the compounds belonging to groups (1) and (2) are listed. The chemical structures of these compounds for labeling are shown in Figure 5.

For the most frequent practical use, stock solutions of the required amine in methanol or tetrahydrofuran containing up to 10% acetic acid are prepared. Immediately before use, an excess of sodium cyano-

- (17) 9-Aminopyrene-1,4,6-trisulfonic acid (FL:  $\lambda_{\text{exc}} = 455$  nm,  $\lambda_{\text{em}} = 512$  nm; Ar-ion laser 488 nm)

borohydride is added to an aliquot of this solution. This solution is mixed with the sample containing the reducing carbohydrates. Finally, this mixture is heated up to 50–80°C from 15 min to 2 h. After the dilution of the reaction mixture, mostly with water, the sample is ready for electrophoresis. By accurately controlling the reaction conditions, the yields of labeled carbohydrates are reproducible, in many cases quantitative. In special cases it is necessary to label the carboxylic group of acid mono- or oligosaccharides with chromophore- or fluorophore-bearing compounds, which is carried out by forming the corresponding amide due to reaction [IV], using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloric as reactive agents. This method was

**Figure 4** Capillary zone electrophoresis of fruit juices: (A) standard mixture (sugars,  $2.22\text{--}2.42\text{ mmol l}^{-1}$ ) and internal standard (glucuronic acid,  $1.15\text{ mmol l}^{-1}$ ); (B) apple juice (diluted 1:50). Running conditions: buffer  $6\text{ mmol l}^{-1}$  sorbate; capillary,  $42\text{ cm}$  ( $35\text{ cm}$  effective length)  $\times 50\text{ }\mu\text{m}$  i.d.;  $230\text{ V cm}^{-1}$ ;  $15^\circ\text{C}$ ; indirect UV detection at  $256\text{ nm}$ ; 1-s injection. 1 = Sucrose; 2 = glucose; 3 = fructose; 4 = glucuronic acid.

applied for labeling of oligosaccharides derived from enzymatic digestion of glycosaminoglycans.

For electrophoretic separation two different kinds of electrolytes are generally used:

1. borate containing electrolytes with pH  $8.5\text{--}10.5$  for the separation of the single-, mono-, and oligosaccharides

2. neutral to slightly acidic electrolytes pH  $2.0\text{--}5.0$  for the separation of the oligosaccharides according to their number of monomeric units.

Figures 6 and 7 show an example for the separation of sugars in both kinds of electrolytes.

**Figure 5** Chemical structures of compounds cited in Table 6 for labeling.

### Capillary Electrochromatography

Capillary electrochromatography (CEC) is a hybrid of CE and liquid chromatography. The separation is carried out in capillaries that are either fully packed with octadecyl-(ODS)-silica particles or partially packed having an open segment. The separation of the analytes is based on the difference in the magnitude of the distribution between the mobile and stationary phase. The flow of mobile phases is generated

by the electroosmosis (EOF) due to the negative charged surface of the silica particles.

CEC was recently applied to the separation of derivatized mono- and oligosaccharides, namely:

- separation of the phenyl-methyl-pyrazolone derivatives of mono- and oligosaccharides;
- separation of 2-aminobenzamide of mono- and oligosaccharides;

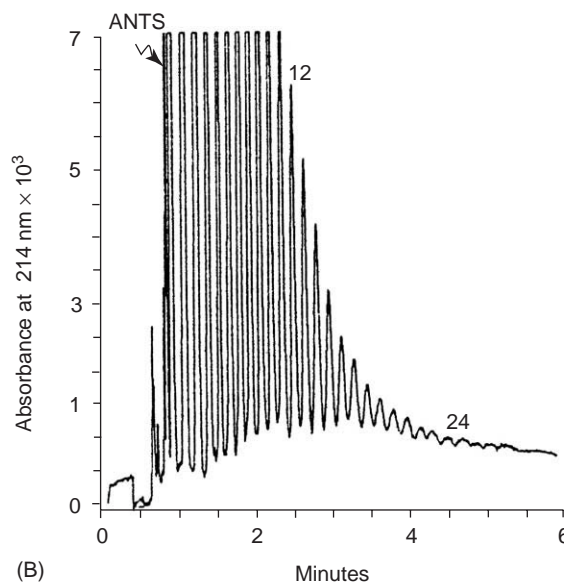

**Figure 6** Separation of mono- and oligosaccharides derivatized with ethyl *p*-aminobenzoate. Capillary: fused silica,  $L=72$  cm,  $l=50$  cm,  $50\text{ }\mu\text{m}$  i.d.; carrier:  $175\text{ mmol l}^{-1}$  borate, pH 10.5; voltage: 25 kV; detection: UV, 305 nm; temperature: 30°C; injection: Vacuum, 1.0 s. Zone identification: R = reagent, 1 = 2-deoxy-D-ribose, 2 = maltotriose, 3 = rhamnose, 4 = cellobiose, 5 = xylose, 6 = ribose, 7 = lactose, 8 = glucose, 9 = arabinose, 10 = fucose, 11 = galactose, 12 = mannuronic acid, 13 = glucuronic acid, 14 = galacturonic acid.

- separation of some *p*-nitrophenylglycosides; and
- separation of glycolipids (neutral and acid glycosphingolipids).

## Microchip Capillary Electrophoresis of Carbohydrates

Microfluidic separation devices have generated considerable interest due to the fact that sample preparation, injection, separation, derivatization, and detection can be integrated into one miniaturized device. A significant amount of effort has been dedicated to the development of diagnostic tools for the benefit of diabetic patients, which resulted in new biosensors and bioassays for monitoring glucose. A glucose/alcohol chip for monitoring glucose and ethanol based on the reaction with glucose oxidase and alcohol dehydrogenase was developed. The detection limits were  $10\text{ }\mu\text{mol l}^{-1}$  for glucose and  $500\text{ }\mu\text{mol l}^{-1}$  for ethanol and the analysis time was less than 100 s.

The catalytic oxidation of the carbohydrates in the presence of Cu(II) for the detection of sucrose, galactose, and fructose was exploited using a Teflon-coated platinum wire plated with copper as the working electrode. Therefore, the addition of copper ions in the run buffer increased the sensitivity to an order of magnitude compared to run buffer without copper. Detection limits were  $\sim 1\text{ }\mu\text{mol l}^{-1}$ .

**Figure 7** Electropherogram of ANTS-derivatized malto-oligosaccharides, obtained at acidic pH at two different temperatures with a  $270\text{ mm} \times 50\text{ }\mu\text{m}$  capillary. (A)  $50\text{ mmol l}^{-1}$  phosphate buffer, pH 2.5; temperature, 25°C; voltage, 15 kV; 22 ng of sample. (B)  $30\text{ mmol l}^{-1}$  phosphate buffer, pH 2.5; temperature, 50°C; voltage, 17 kV; 31 ng of sample. In both cases, the samples were introduced at the cathodic end.

## Introduction

The analysis of human body fluids and tissue extracts by electrophoresis and clinical applications of the technique is one of the most rapidly developing areas of biological research. Whilst analysis of serum proteins by one-dimensional electrophoresis on gel-media or even cellulose acetate still continues to produce

valuable information in the clinical laboratory, capillary electrophoresis and proteomics, including microchip technology, are increasingly becoming the focus of current methodologies and research. Computer analysis of gels produced by sophisticated two-dimensional separation procedures followed by identification of the proteins by mass spectrometry is facilitating the generation of databases on hundreds of proteins in various body tissues and fluids. Changes in sometimes only a few minor components can be correlated with pathological disorders. This article will review techniques currently used in the

analysis of human body fluids (serum and plasma, saliva, cerebrospinal fluid (CSF), urine, and lacrimal fluid) as well as cells and tissues. Uses of electrophoresis in clinical aspects of genetics, virology, and microbiology are also reviewed. Veterinary medicine too is included as this now relies increasingly on this methodology.

Consideration will be given to techniques requiring simple equipment that is inexpensive and readily available in most biomolecular science laboratories, as well as to the more sophisticated procedures that require highly expensive equipment that is available in only a few relatively specialized departments. Although electrophoretic analysis of nucleic acids also continues to be of considerable importance in clinical studies, this review will be concerned mainly with proteins, electrophoresis of nucleic acids having been considered in a separate article.

## Sample Preparation

In the electrophoretic analysis of biological molecules, it is essential to ensure as far as possible that no degradation or modification has occurred between sample collection and analysis. Proteolytic cleavage, deglycosylation, or other degradation by endogenous or bacterial enzymes will give misleading results; cleavage of a single molecule could lead to erroneous conclusions. Samples should, therefore, be stored on ice or frozen immediately after collection (unless freezing also causes changes) and where necessary inhibitors of degradative enzymes or bacterial growth should be added. Samples must not be collected into formal saline or fixed in any way prior to analysis. Because of the sensitivity of some staining procedures, it is also essential to ensure that samples are not contaminated with bacteria (especially in the case of saliva and urine) and that samples are collected into clean sterile containers, otherwise some of the components revealed may originate from contaminant bacteria. The human body is subject to marked circadian variation in its metabolism; accordingly samples should be collected at the same time of day unless changes arising from this variable are known not to occur. Finally, it is essential to ensure that the same size of sample load is applied in all cases where electrophoretic patterns are to be quantified or compared. Unless this is rigorously adhered to, a difference in the presence of a component or its intensity may reflect not a true variation but merely a difference in sample load. Recent improvements in the sensitivity of protein detection methods have largely precluded the need for sample concentration prior to analysis

but when necessary this can be achieved by dialysis followed by lyophilization, ultrafiltration, or acetone precipitation. Problems may still arise from the presence of a component in high concentration masking the component of interest. This can be overcome by removal of the component causing problems by the use of antibody or other affinity-based techniques.

## Technical Considerations

Electrophoretic analysis of clinical samples is usually carried out in a solid support matrix or in liquid systems (capillary electrophoresis). Cellulose acetate has been largely superseded by polyacrylamide gels and agarose gels as a solid support matrix. Although polyacrylamide is probably the most widely used gel medium, the pouring and polymerization of gels can be tedious. Nowadays, an increasingly wide variety of readymade gels is commercially available. Whilst they may be more expensive, they give very reproducible results and avoid the tedium of gel preparation.

Electrophoresis of proteins can be carried out in native (nondenaturing) or denaturing conditions. In the former, the species are separated as a function of charge. In denaturing conditions, usually facilitated by boiling with sodium dodecyl sulfate (SDS) in the presence or absence of a reducing agent such as dithiothreitol, proteins are generally separated as a function of molecular weight. However, whilst this is true for many proteins, unusual amino compositions or post-translational modifications (e.g., glycosylation) can markedly change the migration rate in denaturing gels. Accordingly, this technique is not always a valid indicator of the molecular weight of a protein, especially in the case of clinical samples where many of the proteins may be unusual in some way.

Whilst nucleic acids are normally detected by means of ultraviolet fluorescence in the presence of ethidium bromide or by autoradiography of radio-labeled components, proteins are generally detected by staining procedures or immunoblotting. Coomassie Brilliant Blue (G-250 or R-250) is probably still the most popular protein stain and destaining is relatively rapid. The sensitivity of protein staining can be increased 10–1000-fold by the use of silver-based staining methods. The sensitivity of the staining of proteins by silver-based procedures varies substantially; glycoproteins tend to stain yellow orange and some proteins may not stain at all. More recently, fluorescent stains have become increasingly popular, especially the SYPRO<sup>®</sup> protein stains.

Automated destaining gives more reproducible results than manual. A wide variety of equipment is now available for computerized scanning of stained gels and recording of results. This also enables the storage of vast amounts of information and comparison of gels. Because of the variety of proteins in clinical samples, however, quantitative densitometric measurements on stained components should initially be interpreted with caution. The sensitivity and specificity of protein staining can be increased still further by the use of immunoblotting (Western blotting) and amplification procedures. This involves the probing of gels with a specific antibody, which is then visualized enzymatically or by means of a second radiolabeled antibody.

Although one-dimensional procedures are the easiest and quickest and involve the least sophisticated equipment, substantially more information is produced by two-dimensional procedures. Indeed, it is two-dimensional analysis that has yielded so much new information about the composition of human body fluids and tissues. Successful two-dimensional techniques usually involve separation in the first dimension as a function of charge and in the second as a function of molecular weight. Although separation in the first dimension has generally involved isoelectric focusing in carrier ampholytes, much improved resolution can be obtained by means of immobilized pH gradients, especially at alkaline pH values. Two-dimensional gels of body fluids and cell extracts can reveal several hundred proteins, the complexity of which is such that computer analysis is essential for proper interpretation of the results. It is this technique that has formed the basis of proteomics and facilitated the setting up of databases on the proteins of human body fluids and tissues. With one-dimensional techniques, it cannot be assumed that a single band is a pure component and resolution in a second dimension must always be carried out in order to assess the true degree of purity. The amino acid sequence of pure components from electrophoresis gels can be determined by blotting onto membranes such as poly(vinylidene difluoride) (PVDF), staining, and carrying out sequence analysis on the stained membrane. However, peptides from proteins of interest are now mainly identified by mass spectrometry and the protein characterized by matching these peptides to already characterized proteins in internationally available databases.

Capillary electrophoresis is also now increasingly used in clinical studies. The procedure involves rapid separation in a liquid or gel medium in a microcapillary and requires fairly expensive equipment. Its main advantages are speed of analysis, high sample

throughput, low running costs, versatility, and small sample size (only a few microliters), all of which make it an attractive technique in clinical studies. It can be automated for the analysis of large numbers of samples and the results can be computer recorded and analyzed. Although originally it was best suited for the study of small molecules and ions, its versatility has been extended to include proteins and nucleic analysis and it is now used widely for routine analysis in clinical laboratories. With the advent of microchip electrophoresis, high-resolution separation of microliter samples can be performed in a few hundred seconds.

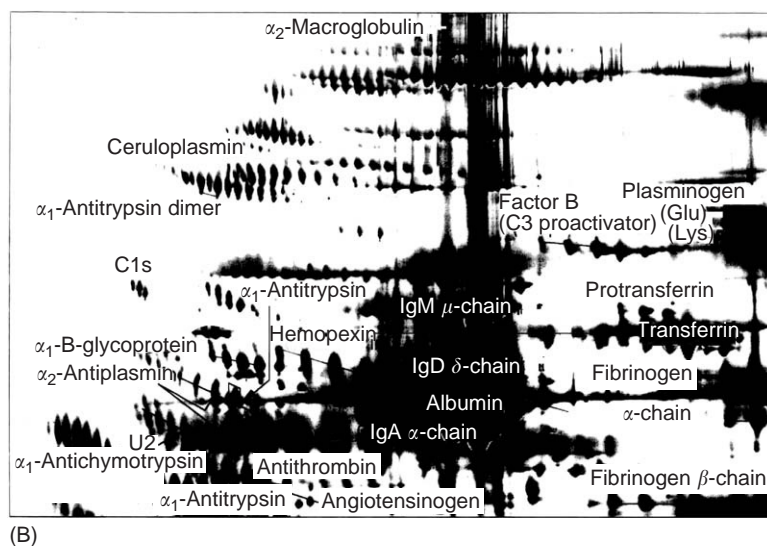

## Human Body Fluids

### Plasma/Serum

Quantitative and qualitative analysis of plasma and serum proteins forms an essential part of the clinical diagnosis of an increasing number of diseases. Electrophoretic separation of these proteins is an integral part of such analyses. Because of its role in tissue-to-tissue transport, changes in plasma protein composition may reflect metabolic disorders in all parts of the body.

One-dimensional analysis using discontinuous buffers in polyacrylamide gel electrophoresis (PAGE) results in 30 or more bands, and a similar number of components can be identified on crossed immunoelectrophoresis. Resolution can be increased to ~60 components by the use of PAGE on gradient gels or isoelectric focusing. The major components are  $\beta$ -lipoproteins,  $\alpha_2$ -macroglobulins, transferrin, albumin,  $\gamma$ -globulins, and paraproteins, with immunoglobulin abnormalities probably being diagnostically the most important. Electrophoresis is used routinely to detect monoclonal gammopathies (paraproteins) in both serum and urine and there are automated systems designed for this purpose. The true complexity of plasma protein composition only becomes properly apparent on two-dimensional analysis. Using isoelectric focusing in the first dimension and SDS gradient-PAGE in the second, followed by silver staining and blotting onto PVDF membranes, ~4000 polypeptides and proteins have now been identified with many, including immunoglobulins, consisting of multiple spots differing in glycosylation or amino acid sequence (**Figure 1**). Spots are characterized by their isoelectric point (pI) and relative molecular mass ( $M_r$ ) in a database or more recently by peptide analysis and mass spectrometry. A high proportion has been identified as known proteins or their derivatives. Despite the complexity of the pattern, which consists of several thousand spots, certain modifications of this protein pattern can be

**Figure 1** Human plasma proteins. (A) Two-dimensional PAGE of human plasma proteins using a pH gradient of 3.5–10.0 in the first dimension and silver stained. Note the focusing of basic proteins as well as the high relative-molecular-mass proteins ( $M_r$ ). (B) Enlargement of the high  $M_r$  area from (A) and (C) the more acidic medium  $M_r$  region from (A). (C)

**Figure 1** (Continued).

associated with specific pathological disorders. The modifications include the presence or absence of components, decreases or increases in intensity of components, or changes in microheterogeneity. The disorders included monoclonal gammopathies, hyper- and hypo- $\gamma$ -globulinaemia, hepatic failure, chronic renal failure, haemolytic anaemia, etc. Monoclonal and polyclonal gammopathies can be differentiated easily on two-dimensional analysis. The literature on detailed changes in plasma/serum proteins associated with a variety of pathological disorders is extensive. The procedures used also involve, for example, zymograms to study isozymes as well as protein staining and antibody-based detection procedures. Capillary zone electrophoresis of serum proteins is now becoming an attractive alternative to agarose- and acrylamide-based techniques.

### Saliva

Human saliva is secreted by three pairs of major glands (parotid, submandibular, and sublingual) and numerous minor ones (labial, buccal, palatine, and glossopalatine). Whilst the parotid glands are the major contributors to stimulated saliva, in the resting state much of the fluid present in the mouth is the viscous submandibular/sublingual secretion, together with the products of the minor glands. Mixed or whole saliva (oral fluid) consists of the secretions of the major and minor glands together with gingival exudate (crevicular fluid), microorganisms, and cell debris. The composition of saliva is modulated on stimulation and subject to circadian variation. The

major proteins in duct saliva are  $\alpha$ -amylase and proline-rich proteins, the latter being comprised of three groups, acidic, basic, and glycosylated. These, together with histidine-rich polypeptides (histatins) and mucins, constitute  $\sim 90\%$  of the protein in parotid duct saliva (**Figure 2**). Antibacterial proteins (lactoferrin, lysozyme, lactoperoxidase, secretory-IgA, etc.), statherin, cystatins, secretory component, and proteins derived from serum (albumin, IgG) comprise the remainder. The major proteins in human saliva are unusual in that they are polymorphic families of proteins that are well suited to separation by electrophoresis. Proline-rich proteins, the functions of which are still unclear, can easily be separated on SDS-PAGE, followed by staining with Coomassie Blue R250 by which they are stained pink-violet. Histidine-rich polypeptides (histatins), which are antifungal and may constitute a non-humoral defense mechanism, are also polymorphic and can be separated by gel or capillary electrophoresis. Because of its viscosity, submandibular saliva is more difficult to collect but electrophoresis is beginning to produce useful new information (**Figure 3**).

Although salivary proteins can be resolved by denaturing or nondenaturing electrophoresis, proline-rich proteins are difficult to detect and currently the only satisfactory method for their analysis is SDS-PAGE. Early attempts to analyze salivary proteins by two-dimensional electrophoresis were unsuccessful, partially because the samples were bacterially contaminated and partially because the pI of the basic proline-rich proteins is too high (pI  $> 8$ ) to remain on

**Figure 2** Human parotid saliva. SDS-PAGE of parotid saliva from eight different individuals (1–8) followed by staining with Coomassie Blue R-250, proline-rich proteins (PRPs) stain pink. MW: molecular weight standards. There are considerable subject-to-subject variations in protein profile; these reflect genetic polymorphisms.

the gel when carrier ampholyte isoelectric focusing is employed in the first dimension. Introduction of immobilized pH gradients in the first dimension has overcome this problem and two-dimensional maps of the major antigens in human parotid saliva have now been produced. Clinical applications of electrophoresis of human salivary protein have been complicated by the fact that all of the major proteins are polymorphic families of proteins that display substantial individual to individual genetic variation.

Connective tissue disorders such as rheumatoid arthritis and Sjögren's syndrome are associated with lymphocyte infiltration of the salivary glands and two-dimensional gels have revealed substantially increased levels of a heterogeneous group of proteins in many of these individuals. Western blots have demonstrated the presence of antibodies to HIV antigens in mixed saliva. One of the basic proline-rich proteins appears to have anti-HIV activity. Although routine clinical applications of electrophoresis of saliva are still limited, this appears to be an area in which there will be considerable developments in the future.

### Cerebrospinal Fluid

The choroid plexus produces ~70% of the CSF, the remainder being produced by the brain and spinal

chord parenchyma. Normally, 80% of the proteins are derived from plasma by diffusion across the blood–CSF barrier and the remainder are synthesized locally. The analysis of CSF protein by electrophoresis is of considerable diagnostic value in neurology. The protein concentration range is ~0.05–0.6 g l<sup>-1</sup>; accordingly, samples may need concentration prior to analysis.

In many cases, a substantial amount of useful information about the protein profile of CSF and any abnormalities can be obtained on one-dimensional electrophoresis. Agarose gels give good results and are easy to prepare. SDS-PAGE gives higher resolution and isoelectric focusing gives even better resolution, especially in the case of immunoglobulins. The gels required are now commercially available. Because some of the oligoclonal bands have high pIs, systems involving immobilized pH gradients give even better results. As with most body fluids and tissue extracts, the time, nature, and complexity of CSF proteins is only properly revealed on two-dimensional analysis, with several hundred or more spots having been reported.

The proteins in normal CSF are similar to those in serum but at lower concentrations. Albumin is the most abundant. Any defect in the blood–brain or blood–CSF barrier leads to an increase in the level of serum proteins. CSF-specific proteins are also

**Figure 3** Human submandibular saliva. This gel shows the proteins in human submandibular saliva separated on a 4–12% Bis–Tris NuPAGE gel and stained with Coomassie Brilliant Blue R250. Samples 1, 2, and 3 are from three different subjects, in which the sample in track ‘O’ is from a gland from which obstructive calculi had been removed 6 months previously and ‘C’ is the contralateral normal control. Equal volumes of sample were applied to each track. On recovery from obstruction, the protein profile is similar to the controls, but the increased band intensity results from a higher protein concentration. (Courtesy of Proctor GB and Osailan SM, Kings College, University of London.)

present, the levels of which may be increased, decreased, or altered in neurological disorders. Immunoglobulins are not normally synthesized in CSF; they enter by diffusion, constitute ~10% of the total protein, and are predominantly IgG. In inflammatory conditions, lymphocytes migrate into the CNS leading to increased levels of IgG, which are readily resolved by isoelectric focusing. In multiple sclerosis, structurally restricted IgG of reduced heterogeneity is produced in the CSF.

Diagnostic studies on oligoclonal IgG, however, are better carried out by two-dimensional analysis. Characteristic changes in CSF proteins derived from the CNS have been associated with CNS disorders such as amyotrophic lateral sclerosis and Huntington’s chorea. Increased  $\alpha_2$ -haptoglobin levels are associated with Alzheimer’s disease and schizophrenia and an increase in apolipoprotein E with low back pain. The establishment of two-dimensional databases of CSF proteins will be of considerable

**Figure 4** Human platelet proteome. Proteins from human platelets (100  $\mu$ g protein) were separated by two-dimensional gel electrophoresis using isoelectric focusing in the first dimension in a pH 3–10 gradient and SDS-PAGE in the second using a 10% 1.5 mm gel followed by silver staining. The relative molecular masses ( $M_r$ ) and isoelectric points of the proteins (pI) separated are indicated. (Courtesy of Maguire PB, Royal College of Surgeons of Ireland.)

assistance in the further development of clinical analysis of CSF.

### Urine

Although it was more than two centuries ago that proteinuria was associated with various diseased states, only since the advent of modern electrophoretic analysis has the potential diagnostic information on the proteins present in urine become apparent. Normal urine has a very low protein content, which necessitates concentration and dialysis of samples prior to analysis. This may lead to some protein loss prior to electrophoretic analysis by some of the earlier procedures. Microscale SDS-PAGE techniques followed by silver staining, however, do not require prior sample concentration and preparation and in some cases of proteinuria dilution may be necessary. One microliter samples of normal urine (protein concentration  $<0.01 \text{ mg ml}^{-1}$ ) reveal one minor band corresponding to albumin. Orthostatic proteinuria is associated with increased excretion of glomerular proteins (albumin, transferrin, IgG), whilst in postrenal haematuria, the additional proteins are similar to those of blood haemolysate, all of the plasma proteins being present. Other postrenal proteinurias are associated with increased levels of proteins such as IgG, monoclonal gammopathies, changes in Tamm–Horsfall glycoprotein, and the

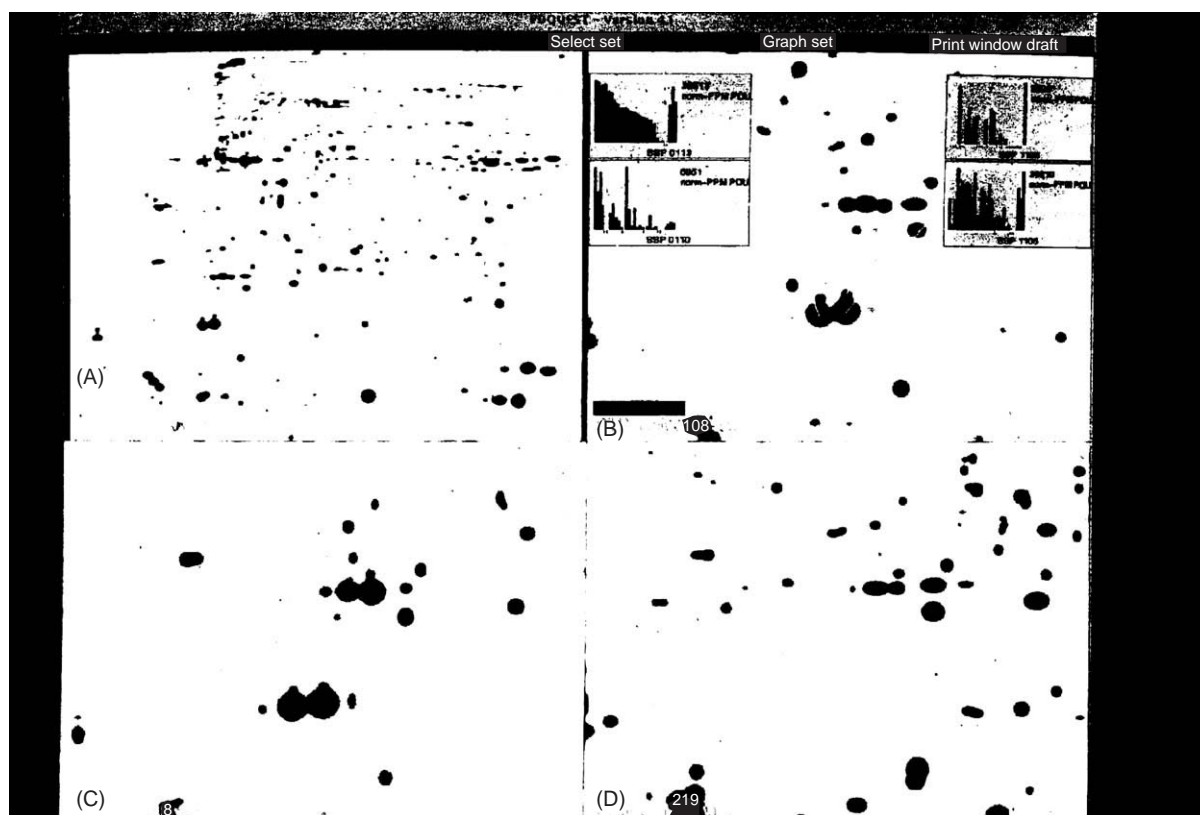

presence of Bence-Jones proteins. The presence of  $\alpha_1$ -microglobulin and increased levels of albumin and transferrin would be indicative of renal complication. Lower and upper urinary tract infections (cystitis and pyelonephritis) can also be associated with increased levels of specific proteins in urine, the nature of which is indicative of the site of infection. In type 1 diabetes mellitus, microalbuminuria occurs in the early stages of nephropathy and the changes in the nature of the proteinuria that occur as the disease progresses can be conveniently monitored by electrophoretic analysis. Electrophoresis (both gel based and capillary) is now used for the analysis of nephrolithiasis-related compounds. Accordingly, micro-SDS-PAGE now affords a fast, simple, and reliable technique for the routine clinical analysis of urine samples without any prior treatment. However, capillary electrophoresis, which offers many advantages over conventional procedures, also gives high resolution of urinary proteins and is becoming increasingly used for clinical analysis of this fluid also.

### Tears (Lacrimal Fluid)

Two-dimensional electrophoretic analysis of tear proteins followed by immunoblotting has shown that the major components are lactoferrin, lysozyme, albumin, secretory IgA, and five tear-specific proteins. There are significant differences in the amounts of lactoferrin and two kinds of tear-specific proteins differ between the sexes. A comparison of the two-dimensional electrophoretic patterns of tear proteins from patients with conjunctivitis with normal individuals shows reductions in the levels of IgA, lactoferrin, and tear-specific proteins whilst the intensity of albumin is increased; in addition, haptoglobin and IgG are present in the patient samples.

### Cells and Tissues

Although electrophoresis of body fluids can produce valuable clinical diagnostic information, changes

in the composition of these fluids merely reflects metabolic changes in the tissues from which the components originate. Tissue and cell analysis, therefore, offers the potentiality of being more specific in pathological investigations and characteristic patterns have been associated with them. High-resolution two-dimensional-PAGE of tissue extracts results in over 2000 proteins being separated from only a few micrograms of tissue, and some of the patterns produced are disease associated. **Figure 4** shows the proteome of a human platelet. Databases have been generated for most body cells and tissues. Two areas of specific interest in tissue analysis are cancer and heart disease.

### Cancer Cells

Whilst alterations in cancer cells are likely to be at the DNA or chromosomal level, proteome analysis of

**Figure 7** Protein profiles of virally infected cells. Two-dimensional protein profiles of rhabdomyosarcoma cells (A) uninfected and (B) infected with Cocksackie B5 virus. The proteins were labeled and located by autoradiography. The three proteins p39, p54, and p75 are specific for the infected cells. tumor cells and body fluids is now widely used in cancer research as a tool for the identification of tumor markers and the development of molecular diagnostic markers for its early detection. The technique complements other aspects of cancer research and produces information that cannot be obtained otherwise. Because of the complexity of the polypeptides in whole cell extracts, analysis of subsets of proteins (e.g., membrane, cytoplasmic, nuclear) not

**Figure 8** Canine serum. One-dimensional gel electrophoresis of dog serum separated on SDS-PAGE followed by silver staining. only simplifies the results but can also facilitate detection of proteins that are below the levels of sensitivity in whole cell preparations. When comparing transformed and nontransformed cells qualitatively, there can be remarkable similarity in their polypeptide patterns but quantitatively there are substantial variations. The procedure can also be applied in the detection of lineage markers in cancer cells and the study of polypeptides secreted by them, as well as monitoring the progress of the disorder.

### Cardiac Disease

Databases have been produced for myocardial tissue proteins in order to elucidate the nature of protein expression in normal and disease conditions. **Figure 5** shows a computer-generated image of a two-dimensional-PAGE separation of human heart proteins with regions showing alterations in the pattern that are associated with heart disease. The most serious complication of cardiac transplantation is accelerated coronary artery disease that may result from endothelial cell damage mediated by antiendothelial cell antibodies produced as a result of the transplant. Western blotting of human umbilical cord endothelial cells with sera from post-transplant patients with coronary artery disease showed the presence of antiendothelial cell antibodies that were rare in post-transplant patients without coronary artery disease (**Figure 6**).

**Figure 9** Canine urine. One-dimensional SDS-PAGE electrophoresis of the proteins in dog urine from two different animals before and after castration. After castration the pattern is similar to that of females. Differences in levels of the male-specific protein (indicated by an arrow) may be associated with different prostate disorders. (Courtesy of Miller I, University of Veterinary Medicine, Vienna.)

### Genetics

Electrophoresis has facilitated substantial developments in the study of genetics ranging from one-dimensional electrophoresis of enzyme polymorphisms to the use of DNA electrophoresis in the human genome project, which culminated in the sequencing of the entire human genome. Gel electrophoresis of DNA fragments is now widely used in the investigation of genetic defects that affect human health and has led to substantial developments in the understanding of inherited disease at a molecular level. Mutations in the base sequence also lead to changes in the size of fragments formed on degradation by restriction nucleases. Where appropriate, specific genes (DNA fragments) can be targeted and amplified by the polymerase chain reaction (PCR).

Electrophoretic separation of proteins (the gene products and their post-translational modifications) continues to be an essential tool in the study of genetic polymorphisms and inherited diseases. Detection methods for the proteins of interest include

protein staining, zymograms, Western blotting, and isotopic labeling. In many cases, the product of the mutant gene is unknown. In such cases it is now possible to clone the gene involved and characterize its product, i.e., 'reverse genetics'.

## Virology

Molecular techniques are now being used increasingly in the study of viral infections. They are especially useful either as a supplement to existing serological techniques or as an alternative when such techniques do not exist.

Electrophoretic analysis of viral nucleic acid has played a major role in investigating and characterizing viruses as well as bacteria. Analysis of virally induced proteins in one-dimensional SDS-PAGE has been used to differentiate clinical isolates of certain viruses; one-dimensional IEF has been used to differentiate foot-and-mouth disease virus isolates from cattle. As in all cases of one-dimensional analysis of proteins, two-dimensional PAGE gives improved resolution and portrays the vast numbers of proteins that are present in the sample. Accordingly, analysis of proteins from virally infected cells has facilitated the identification of proteins characteristic of certain viral infections and yielded new information about gene expression in viruses including foot-and-mouth disease, polio, and Cocksackie B viruses. **Figure 7** shows some of the differences in protein profile of a Cocksackie B infected cell compared with an uninfected one.

## Microbiology

The majority of bacterial typing in the past has been based on phenotypic or readily observable characteristics. Although these procedures are still the method of choice in many cases in the routine laboratory analysis, typing procedures based on electrophoretic analysis of nucleic acids, especially PCR and gene probing, are becoming increasingly used in bacterial identification.

Electrophoretic analysis of bacterial proteins also produces a pattern that is characteristic of the particular bacterial strain and bacterial proteomes are now well documented. This technique now plays a key role in many areas of medical microbiology including gene expression, epidemiology, taxonomy of pathogens, and drug resistance. Numerous strains of bacteria have now been studied by this procedure. Capillary electrophoresis is also gaining in popularity for the analysis, identification, and characterization of microorganisms. The advantages include small sample size, ease of quantification, and identification and rapid simultaneous analysis.

## Veterinary Clinical Studies

Advances in laboratory-based veterinary clinical studies have been accompanied by the increased use of electrophoresis-based techniques both in the routine clinical and research laboratory. Variations in the composition of serum, urine, and other body fluids and tissues of animal origin are all possible markers of health and disease. They offer

**Figure 10** Bovine milk proteins. Two-dimensional PAGE analysis of proteins from bovine milk: (A) normal milk and (B) milk from animals with mastitis. The proteins were separated in the first dimension by isoelectric focusing in a pH gradient of 4–7 and in the second dimension by SDS-PAGE electrophoresis in a 12% gel followed by staining with Brilliant Blue G colloidal stain. In the mastitic milk, most of the proteins (casein,  $\beta$ -lactoglobulin, and  $\alpha$ -lactalbumin) have been lost, and the major proteins are now of serum origin (albumin, serotransferrin). (Courtesy of Hogarth CG, University of Glasgow.)

considerable potential not only in animal welfare and care, but are also of growing economic importance in livestock management. Animal serum proteomes are now being established and serum protein reference maps have been established for cows, dogs, rats, and pigs. Currently, studies are largely focused on the inflammatory process and gammopathies, where serum analysis can yield valuable information (**Figure 8**). Other body fluids (e.g., urine) are also revealing interesting new findings (**Figure 9**) and the technique may also be of value in the early diagnosis of mastitis (**Figure 10**).

Although one-dimensional electrophoretic analysis of proteins continues to produce valuable information in the clinical laboratory, 2D-analysis of proteins, computer analysis of gels, mass spectrometry based identification procedures, proteomics and the formation of international databases, which are readily accessible on websites have opened up a new dimension in clinical diagnostic procedures. With the completion of the human and bacterial genome projects, although nucleic acid based studies, will continue to be high profile in clinical studies, future developments are likely to be centered increasingly on gene products and their post-translational modifications, i.e., proteins.

## Introduction

Electrophoresis is an essential technology for the separation and analysis of nucleic acids. Electrophoresis of nucleic acids is used routinely at the lab bench for the isolation and manipulation of cloned DNA fragments. In addition, it is a critical component of many molecular biology protocols that assess the role and interaction of nucleic acids in cells and tissues. Nucleic acid electrophoresis has attained particular importance in the current era of genome

sequencing. In this application, speed and accuracy of nucleic acid analysis are of vital scientific and economic interest, and the practice of nucleic acid electrophoresis has evolved to reflect these needs. In this article, the physicochemical aspects of nucleic acid electrophoresis are outlined and the major techniques utilized for the electrophoresis of nucleic acids are described.

## Nucleic Acid Structure and Electrophoretic Mobility

Due to their phosphate groups, nucleic acids are negatively charged at all but the most acidic of pH

conditions. In fact, because each base carries a phosphate moiety, the charge-to-mass ratio of nucleic acids is essentially independent of size and form (e.g., single stranded versus double stranded, linear versus plasmid). As a result, nucleic acids migrate readily in an electric field from the cathodic to anodic (negatively to positively charged) ends of the apparatus. For separation and analysis of nucleic acids, therefore, an additional discriminatory parameter is needed. Most frequently, this is accomplished by electrophoresis through a sieving medium, i.e., a gel, through which small molecules will pass more easily and larger ones will pass more slowly, due to the combined effects of sampling a greater fraction of the gel space and hindered transport (volume exclusion) effects.

For a small, spherical particles, the balance of electric and viscous forces results in an electrophoretic mobility ( $u$ , defined as the particle velocity per applied electric field strength) given by

$$u = \frac{q}{6\pi R\eta} \quad [1]$$

where  $q$  is the charge on a particle of radius  $R$  and  $\eta$  is the solvent viscosity. The formation of higher-order structures by nucleic acids will cause considerable deviation from this behavior, and indeed electrophoresis is used to ascertain the physical form of DNA. Condensed (e.g., supercoiled) DNA behaves most closely to a spherical particle, whereas linear DNA exhibits mobility that reflects its polymeric nature. That is, the DNA is thought to reptate through the pores of the gel in a wriggling, snake-like manner. However, double-strand formation and counterion condensation serve to decrease the flexibility of the nucleic acid, and as a result the reptating nucleic acid behaves more as a stiffly jointed rod in its transport through a sieving gel. A consequence of this behavior is that for high molecular weights, the 'tail' of the DNA chain no longer samples a distribution of pore space, and the mobility becomes independent of chain length. Thus, separation of very high (>60 kbp) molecular weight DNA requires other techniques, such as pulsed-field gradient electrophoresis.

Thus, under constant applied electric field, the mobility is determined primarily by the pore size of the gel matrix. In this case the so-called Ferguson plot gives the relationship between the gel concentration and the electrophoretic mobility (sieving effect). In this method, the logarithm of the electrophoretic mobility is plotted as a function of gel concentration. The intercept of this plot may be interpreted as being related to the charge on the solute and the intercept as related to its size or shape. Conversely, the separation and analysis of nucleic

acids can be tuned by selection of an appropriate matrix and composition (Table 1). Other electrophoretic parameters, such as applied field strength and temperature, have an effect on the mobility of the different chain length nucleic acids and on the separation efficiency.

## Detection

Nucleic acids in solution can be detected and quantified readily on the basis of ultraviolet (UV) absorbance. Nucleic acids exhibit strong absorbance with a peak at 260 nm in a manner that is sensitive to chemistry and bonding. For accurate quantification of small oligonucleotides, a sequence-dependent extinction coefficient can be computed, but for all other routine laboratory analysis, approximate values are almost universally employed (Table 2).

For in-gel analysis of double-stranded DNA, ethidium bromide (EtBr) is still the most widely applied dye. EtBr intercalates between base pairs of the DNA, resulting in the production of fluorescence, which can be observed either by broad UV illumination (excitation maxima at 254, 302, and 366 nm) or by laser excitation at 514 nm and detection at 590 nm. Agarose gels may be either cast in the presence of EtBr or stained with the dye solution afterward; acrylamide gels must be stained after electrophoresis as ethidium inhibits the polymerization of acrylamide. The limit of detection with EtBr is on the order of 10 ng. Because EtBr changes the physical properties of DNA, most notably its stiffness, prestaining is not appropriate for DNA in

**Table 1** Separation ranges for agarose and acrylamide gels

% Agarose	Range (kb)	% Acrylamide monomer	Range (bp)
0.3	5–60	3.5	100–1000
0.6	1–20	5.0	80–500
0.7	0.8–10	8.0	60–400
0.9	0.5–7	12.0	40–200
1.2	0.4–6	15.0	25–150
1.5	0.2–4	20.0	6–100
2.0	0.1–3		

**Table 2** Concentration of nucleic acids giving one absorbance unit (i.e., absorbance = 1.0)

Nucleic acid	Concentration for $A_{260} = 1.0$
dsDNA	50 $\mu\text{g ml}^{-1}$
ssDNA	33 $\mu\text{g ml}^{-1}$
RNA	40 $\mu\text{g ml}^{-1}$

assays designed to assess physical form (e.g., supercoiling). On the other hand, the displacement of EtBr can be used as a means to monitor the complexation of DNA with cationic polymers used for nonviral gene delivery.

The most sensitive detection of nucleic acids is accomplished by radiolabeling. Single-stranded DNA is readily 5'-end labeled using T4 polynucleotide kinase. RNA species transcribed *in vitro* or DNA generated by PCR may be radiolabeled by the inclusion of a fraction of isotopic dNTPs in the polymerase reactions. Probes to be used for Northern or Southern blotting can be labeled using a variety of methods; common ones include random priming from a DNA template, primer extension, and end-labeling using the Klenow fragment of *Escherichia coli* DNA polymerase I.

With improvements in chemical dyes and fluorescence scanning instrumentation, DNA electrophoresis is performed increasingly using fluorescent dyes as the means for detection. Single-stranded oligonucleotides are synthesized readily with fluorescent dyes at the 5'- or 3'-ends, albeit that the latter significantly reduces the yield of the synthesis. Most commonly, fluorescein derivatives such as FAM (carboxy fluorescein) are utilized, but many other dyes have been incorporated as well. Plasmid DNA can be labeled using commercial reagents that place amine or carboxyl groups onto guanine residues, which are then used to attach Cy3, rhodamine, or other dyes. As an alternative to EtBr, SYBR Gold and SYBR Green effectively bind to double-stranded DNA and to a lesser extent, single-stranded DNA. Dyes specific for single-stranded oligonucleotides (e.g., OliGreen) exist as well, but they have been tested less extensively for gel detection.

## Slab Gel Electrophoresis

Electrophoresis is most commonly performed in a slab gel format, which can be used in either the vertical or the horizontal configuration. Slab gels are relatively easy to form and provide a mechanically stable medium with an extended surface area to reduced thermal convection (though they are vastly inferior to capillaries in this regard – see following section). It is possible to excise separated bands from a gel, and thus perform batch separations using electrophoresis.

### Materials

The two materials used most commonly for DNA slab gel electrophoresis are polyacrylamide and agarose. Polyacrylamide gels are formed with pore

sizes that depend on the percentage of acrylamide used as well as the proportion of cross-linker, *N,N'*-methylene bisacrylamide. Acrylamide monomer concentrations range from 3.5% to 20%. The polymerization reaction is generally carried out directly to form a slab in a mold. Details and specific protocols are provided in the volume by Sambrook. Excellent – down to single base – resolution of nucleic acids is achieved using polyacrylamide gels, and as a result they are used for DNA sequencing.

Agarose is a polymer of D-galactose and 3,6-anhydrogalactose and is used in concentrations ranging from 0.3% to 2.0% (Table 1). The agarose gel is formed when the constituents are heated and then cooled under ambient conditions to room temperature. Agarose is used for higher molecular weight separations due to the larger pore sizes and the ability to maintain mechanical stability at low weight percentages. An additional advantage of agarose is that it can be easily dried to a thin, transparent film, which makes it quite suitable for autoradiography.

### Operations and Applications

The buffers used for electrophoresis can be categorized as nondenaturing and denaturing. Because double-stranded DNA is dominated by secondary structure rather than by high-order structure under many conditions, nondenaturing electrophoresis is sufficient for many applications. Sometimes, a denaturant such as urea is introduced when it is critical to minimize higher-order effects. This is particularly common in the analysis of oligonucleotides by polyacrylamide gel electrophoresis (PAGE) for applications such as sequencing. Single-base resolution is obtained for sequencing gels, which are run vertically.

For the separation of very large DNA molecules (>20 kb), pulsed field gel electrophoresis (PFGE) is employed. In PFGE, two sets of electrodes are used to alternately generate current in transverse directions. When the electric field changes directions, the DNA molecules must reorient themselves in the gel to begin moving in a new direction. The ability of the DNA to reorient is length dependent, forming the basis for the PFGE separation. As DNA molecules up to 10 Mb can be resolved by PFGE, this technique is finding applicability for gene–chromosome mapping in lower eukaryotes and for long-range restriction mapping in higher eukaryotes, whose complete chromosomes are too large for even PFGE separation.

Separation of nucleic acids is used routinely at the lab bench, for example, to isolate cloned DNA, to purify *in vitro* transcribed RNA, and to recover transcripts differentially expressed in disease or other conditions of interest. The identification of nucleic

acids from cells and tissues, using techniques such as Northern and Southern blotting, and reverse transcriptase-polymerase chain reaction (RT-PCR), is critically dependent upon electrophoresis. In the Northern and Southern blotting techniques, which are used for analysis of RNA and DNA, respectively, the nucleic acids are electrophoresed twice. First, they are separated by electrophoresis on an agarose gel. Then, they are transferred to nitrocellulose or nylon membranes by electrophoresis in the direction perpendicular to the gel. Detection of specific DNA or RNA molecules in the blot is performed using a complementary probe DNA that is labeled either radioactively or fluorescently as described above. The relative size, as determined by position on the gel relative to molecular weight markers, provides confirmation of the identity of the target RNA or DNA.

Electrophoretic mobility shift assays are used to characterize the binding of nucleic acids to other molecules. The traditional application is to protein-DNA interactions, in which proteins are separated in a PAGE gel and probed with a labeled double-stranded oligonucleotide with a sequence corresponding to the consensus for the DNA binding site of interest. This methodology can be applied in additional areas, most notably the characterization of polymer-DNA interactions in nonviral gene and oligonucleotide deliveries. Depending on the characteristics (e.g., chemistry, molecular weight, degree of branching) of a particular delivery polymer, the charge ratio (cationic polymer-anionic DNA) at which complex formation occurs can vary widely. This is assessed by a gel shift assay in which the disappearance of the band owing to labeled (or stained) free DNA is followed.

## Capillary and Capillary Gel Electrophoresis

The advent of high-performance capillary electrophoresis (HPCE) operating at electric field strengths of up to  $1000\text{--}1500\text{ V cm}^{-1}$  has enabled the technique to be used for the rapid multicomponent analysis of single-stranded oligonucleotides and double-stranded DNA fragments. The use of capillaries allows the heat generated by such high field strengths to be dissipated, and allows the use of sample volumes less than a microliter. The method is sensitive enough to detect differences in the secondary structure of nucleic acid molecules that are of the same size, has micropreparative capabilities, and offers the ability to detect samples online. The high efficiency and speed of this approach makes it useful as a means of assessing the purity of nucleic acid

molecules produced by a DNA synthesizer and for PCR products. The method is also seeing extensive application in DNA sequencing.

## Materials and Equipment

In HPCE, samples can be detected on-column (online). Removing the polyimide coating of the fused silica capillary in a small section allows UV or fluorescent detection. A power supply is used to apply a field strength of  $0\text{--}30\text{ kV}$ . Injections can be made by means of pressure or electrokinetic modes that allow the application of automated injection systems.

In polyacrylamide capillary gel electrophoresis, the gel is usually polymerized *in situ* in the capillary tubing. The polyacrylamide is entirely synthesized from monomers, either with or without cross-linking, depending on the application. These gel columns are employed in the size separation of biologically important polymers such as DNA or RNA. The high efficiency and speed of this approach makes it useful as a means of assessing the purity of nucleic acid molecules produced by a DNA synthesizer, for PCR products, and for DNA sequencing.

## Operations and Applications

In the size separations of oligodeoxyribonucleotides and oligoribonucleotides by capillary gel electrophoresis for chain length determination, denaturing agents should be used in the buffer system to avoid intra- and interchain interactions and therefore the formation of secondary structures. In PAGE,  $7\text{--}9\text{ mol l}^{-1}$  urea or  $30\text{--}70\%$  formamide is used as a denaturing agent. The primary sequence of the oligomers can have a significant effect on electrophoretic mobility. By changing the pH of the gel buffer, the separation power of the system can be altered.

Complexing agents, charged or uncharged, can be simply added to the gel-buffer system. Complexation can speed up or slow down the migration velocity of the solute. In the separation of double-stranded DNA fragments, an intercalator additive such as EtBr can be used as a complexing agent in order to enhance the separation power of the method. EtBr is positively charged at the pH of the running buffer; thus, it decreases the effective charge of the DNA molecule. As a result, the DNA-EtBr complex migrates more slowly under the same applied electric field, increasing in this way the separation time window and enhancing separation efficiency.

Capillary electrophoresis (CE) is now the technique of choice for analysis of nucleic acids when small sample volume and high resolution are important considerations. Large-scale sequencing efforts are conducted presently using electrophoresis in arrays

of capillaries. In addition, CE is being applied to the detection of genetic mutations through dideoxy fingerprinting and to DNA adduct formation. For efficient separations of DNA in CE, linear polyacrylamide solutions of low viscosity and coated capillary surfaces are used. These are not ideal, however, and the tailoring of polymer solutions to particular separation needs is an active area of research. In the future, the marked improvements in microtechnology promise to bring about microfabricated sequencing arrays, the proof of principle for which has already been established. This approach can be easily integrated with microfluidics to develop 'lab-on-a-chip' devices. Instruments such as the Agilent Bioanalyzer are already capable of performing rapid, quality control analyses on-chip with 1 µl or less of sample.

## Introduction

Proteins are, together with nucleic acids, the most important biomolecules. Acting as enzymes, enzyme substrates and inhibitors, hormones, receptors, structural units, antigens, antibodies, drugs, and toxins, they play a vitally important role in all living organisms. In the current era of proteomics, the comprehensive analysis of the proteome, i.e., analysis of the set of all proteins encoded by the genome of a given organism and expressed in cells, tissues, or organs at a particular time and particular conditions, which nowadays represents the main approach for a complete understanding of biological systems and new drug discovery, the importance of proteins is ever increasing.

The huge number of variations of amino acid sequences in protein molecules and variety of attached prosthetic groups result in an extraordinary diversity of proteins that differ in electric charge, size, shape, specific binding capabilities, and, consequently, in electrophoretic mobilities, which allows their separation using different electrophoretic

methods:

1. zone electrophoresis (ZE) and isotachopheresis (ITP) in free-solution media – based on different charge-to-size ratios of proteins;
2. ZE in sieving media (gels and entangled polymer networks) – based on size-dependent retardation of electromigration of proteins by the medium matrix;
3. isoelectric focusing (IEF) – based on different isoelectric points of proteins; and
4. (bio)affinity electrophoresis (BAE) – based on influencing the electromigration of proteins through specific interactions with other (bio)molecules in separation media.

All these separation modes can be performed in different instrumental formats. The first electrophoretic separations of proteins were performed by Tiselius in a free solution in a U-tube macrocuvette, allowing refraction index detection of boundaries of protein zones. Soon it was found out that the separation would be more efficient if performed in anti-convective stabilizing medium; thus electrophoresis started to be performed in different carriers (paper, acetyl cellulose membrane) or in gel media (starch, agar, agarose, polyacrylamide (PAA)). In the last two decades electrophoresis has reverted to the free solution, stabilized by the anticonvective capillary effect of microbore (inner diameter (i.d.) < 100 µm)

of capillaries. In addition, CE is being applied to the detection of genetic mutations through dideoxy fingerprinting and to DNA adduct formation. For efficient separations of DNA in CE, linear polyacrylamide solutions of low viscosity and coated capillary surfaces are used. These are not ideal, however, and the tailoring of polymer solutions to particular separation needs is an active area of research. In the future, the marked improvements in microtechnology promise to bring about microfabricated sequencing arrays, the proof of principle for which has already been established. This approach can be easily integrated with microfluidics to develop 'lab-on-a-chip' devices. Instruments such as the Agilent Bioanalyzer are already capable of performing rapid, quality control analyses on-chip with 1 µl or less of sample.

## Introduction

Proteins are, together with nucleic acids, the most important biomolecules. Acting as enzymes, enzyme substrates and inhibitors, hormones, receptors, structural units, antigens, antibodies, drugs, and toxins, they play a vitally important role in all living organisms. In the current era of proteomics, the comprehensive analysis of the proteome, i.e., analysis of the set of all proteins encoded by the genome of a given organism and expressed in cells, tissues, or organs at a particular time and particular conditions, which nowadays represents the main approach for a complete understanding of biological systems and new drug discovery, the importance of proteins is ever increasing.

The huge number of variations of amino acid sequences in protein molecules and variety of attached prosthetic groups result in an extraordinary diversity of proteins that differ in electric charge, size, shape, specific binding capabilities, and, consequently, in electrophoretic mobilities, which allows their separation using different electrophoretic

methods:

1. zone electrophoresis (ZE) and isotachopheresis (ITP) in free-solution media – based on different charge-to-size ratios of proteins;
2. ZE in sieving media (gels and entangled polymer networks) – based on size-dependent retardation of electromigration of proteins by the medium matrix;
3. isoelectric focusing (IEF) – based on different isoelectric points of proteins; and
4. (bio)affinity electrophoresis (BAE) – based on influencing the electromigration of proteins through specific interactions with other (bio)molecules in separation media.

All these separation modes can be performed in different instrumental formats. The first electrophoretic separations of proteins were performed by Tiselius in a free solution in a U-tube macrocuvette, allowing refraction index detection of boundaries of protein zones. Soon it was found out that the separation would be more efficient if performed in anti-convective stabilizing medium; thus electrophoresis started to be performed in different carriers (paper, acetyl cellulose membrane) or in gel media (starch, agar, agarose, polyacrylamide (PAA)). In the last two decades electrophoresis has reverted to the free solution, stabilized by the anticonvective capillary effect of microbore (inner diameter (i.d.) < 100 µm)

fused silica capillaries or microchannels on chips. Due to space limitations, the different modes and instrumental formats of electrophoretic methods can be described here only in brief.

## Electromigration Properties of Proteins

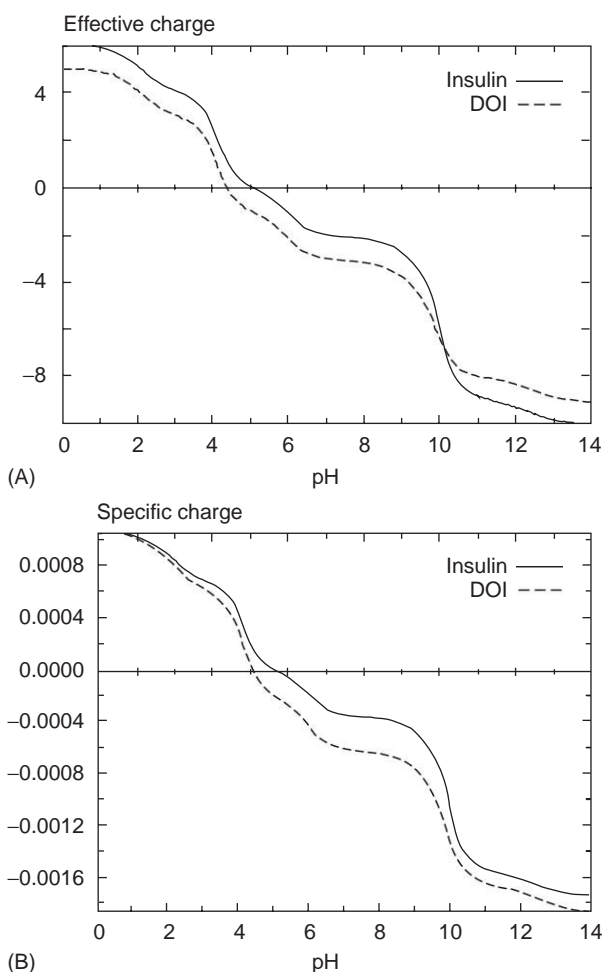

From the physicochemical point of view proteins are amphoteric (poly)electrolytes or (poly)ampholytes containing different types of ionogenic groups, e.g., carboxyl groups of C-terminal amino acids and aspartic and glutamic acids, amino groups of N-terminal amino acids, and side groups of lysine, arginine, and histidine. The basic parameter in electromigration methods of proteins is their electrophoretic mobility,  $m$  ( $\text{m}^2 \text{V}^{-1} \text{s}^{-1}$ ), i.e., their migration velocity related to a unit intensity electric field. The electrophoretic mobility of a protein is a complex function of (1) the properties of the protein itself (charge, size, shape); (2) the properties of the medium (background electrolyte (BGE)) in which the protein is moving (composition, pH, ionic strength, viscosity, permittivity, temperature); and (3) the interactions of the protein with the components of the BGE (solvation, dissociation, complex formation). The protein mobility, related to the given experimental conditions, particularly to the composition, pH, and temperature of the BGE, is called the effective (net) mobility.

The relationship between the effective mobility of a protein,  $m_{\text{ef}}$ , its effective charge,  $z_{\text{ef}}$ , and size (expressed as relative molecular mass,  $M_r$ ) can be approximately described by the equation

$$m_{\text{ef}} = az_{\text{ef}}/[b(M_r)^{1/3} + c(M_r)^{2/3}] \quad (1)$$

where  $a$ ,  $b$ , and  $c$  are empirical constants dependent on the electrolyte system used and on the size and structure of the proteins investigated. As follows from this equation, the mobility of a protein is directly proportional to its charge and indirectly proportional to its relative molecular mass with exponent in the range 1/3 to 2/3.

The effective (net) charge of a protein is given by the sum of the charges (including their signs) of all the ionogenic groups in its molecule. It can be estimated from the amino acid sequence of a given protein if the dissociation constants of the present ionogenic groups are at least approximately known. The calculated pH dependence of the effective charge and the specific charge (effective charge divided by  $M_r$ ) of the 'smallest protein', human insulin, and its polypeptide fragment, des-B23-B30-octapeptide insulin (DOI), is shown in Figure 1. From these curves

**Figure 1** Calculated dependence of (A) effective charge and (B) specific charge (effective charge divided by relative molecular mass) of pig insulin and DOI on pH.

an important characteristic of proteins, the isoelectric point, the pI, i.e., the pH at which the effective charge is zero, can be read, and some other useful information can be obtained, such as the pH regions of the maximal differences of their specific charges, suitable for their separation.

## Electrophoresis in Gels

Among the different gel matrices (starch, agar, agarose, PAA), especially the last two, agarose and PAA, are widely used for electrophoretic separations of proteins.

### Agarose Gel Electrophoresis

Agarose gels are used when nonrestrictive gels with large pores for the separation of macromolecules, proteins and nucleic acids, over 10 nm in diameter, are needed. The gels are prepared by cooling the

agarose (polysaccharide from red seaweed), dissolved in boiling water and poured into layers of different thicknesses, 0.1–2 mm, set on horizontal glass plates or support films. Agarose gels are applied for separations where the sieving effect of the gel matrix should be avoided, i.e., in isoelectric focusing, ITP, and immunoelectrophoretic techniques. In the latter technique a specific antibody is allowed to diffuse or migrate electrophoretically through the gel and to form insoluble immunocomplexes with corresponding antigens, thus detecting them with high specificity and sensitivity due to the high specificity and strength of the antigen–antibody complexes.

Agarose gels with concentrations of 0.7–1% (m/v) are often used in clinical laboratories for analysis of serum proteins and isoenzymes of diagnostic importance such as lactate dehydrogenase and creatine kinase.

### PAA Gel Electrophoresis

PAA gels are particularly suitable for electrophoresis of proteins due to their chemical inertness and controllable porosity. PAA gels are prepared by chemical copolymerization of acrylamide with a crosslinking reagent, *N,N'*-methylenebisacrylamide (or its derivatives). A clear transparent gel with low electroosmosis is obtained. The porosity can be exactly and reproducibly controlled by the total acrylamide concentration,  $T$ , and degree of crosslinking,  $C$

$$T[\%] = (a + b)100/V \quad [2]$$

$$C[\%] = b \times 100/(a + b) \quad [3]$$

where  $a(b)$  is the mass of the acrylamide (bisacrylamide) in grams and  $V$  is the volume of the monomer

solution in milliliters. With increasing  $T$  at constant  $C$ , the pore size decreases; for constant  $T$  the pores are minimal at  $C = 4\%$ . Gels are usually polymerized in vertical casting chambers, cylindrical gels in glass tubes, and slab gels in moulds formed by two parallel glass plates sealed together along the edges. For electrophoresis in vertical systems the gels in glass rods or cassettes are placed in buffer reservoirs with electrodes, through which the electric field is applied to the gel.

For sample application the wells are formed by insertion of a sample comb between the glass plates at the upper edge of the gel during polymerization. In horizontal gels the sample can be introduced directly on the surface with strips of filter paper or silicone rubber.

At first, PAA gel electrophoresis (PAGE) was mostly performed in vertical cylindrical, rod-like gels polymerized in glass tubes of diameter 3–5 mm; later on and nowadays thin layer (0.1–0.5 mm) gels, both in the vertical and horizontal orientation, with or without cooling, are preferred because of faster, more efficient, and more sensitive separations.

**Discontinuous PAGE** Discontinuous PAGE (Disc-PAGE) is electrophoresis in a discontinuous electrolyte system. This discontinuous (isotachophoretic) or multiphasic buffer system consists of two different buffers, the leading electrolyte (Tris–HCl) and the terminating electrolyte (Tris–glycine), in two different gels. The sample is loaded on a large-pore stacking gel containing a lower pH (6.8) and lower concentration ( $0.125 \text{ mol l}^{-1}$ ) Tris–HCl buffer (see Figure 2). The large-pore stacking gel is polymerized on the top of the small-pore resolving gel containing a higher pH (8.8) and higher concentration

**Figure 2** Principle of discontinuous PAGE. (Reproduced with permission from Westermeier R (1997) *Electrophoresis in Practice: A Guide to Methods and Applications of DNA and Protein Separations*. Weinheim: Wiley-VCH; © Wiley-VCH.)

( $0.375 \text{ mol l}^{-1}$ ) Tris-HCl buffer. In both these gels and in the anode reservoir the chloride anion acts as the leading ion of the anionic ITP electrolyte system. The glycinate anion of the Tris-glycine buffer placed above the stacking gel and in the cathode reservoir serves as the terminating ion.

The main advantage of discontinuous buffer systems over continuous ones, which use a uniform buffer of constant pH, is that relatively large volumes of dilute protein samples without preliminary sample concentration can be applied to the gels. Due to the concentrating and self-sharpening effects of the ITP buffer system, proteins are concentrated into narrow zones during their migration in the large-pore gel, thus forming a suitable starting zone before entering the small-pore gel, in which size-based separation takes place in the ZE mode in the Tris-glycinate buffer. High-resolution separation is achieved due to both anticonvective and sieving effects of the PAA gel. When Disc-PAGE is performed in PAA rods, the well-defined and resolved proteins zones have a form of narrow disks, which is the second origin of the name disk-electrophoresis.

**Pore gradient gel electrophoresis (PGGE)** Soon after electrophoresis was established in the PAA gel, it was understood that the high resolution of proteins in this medium was achieved mainly due to a molecular sieving mechanism, differentially retarding proteins according to their size. This effect is exploited for size-based electrophoretic separation of proteins in gels with changing gel porosity, i.e., in PGGE. Pore gradient gels are prepared by varying the acrylamide concentration in the polymerization solution. The proteins are forced to migrate through progressively smaller pores until they reach a point where, due to their size, they are trapped in the tight gel matrix. PGGE can be used for estimation of the size (diameter or  $M_r$ ) if proper size calibration of the gel porosity is performed.  $M_r$  values can be obtained also from the so called Ferguson's plot, i.e., from the linear dependence of the decadic logarithm of the relative mobility ( $R_f$ ) of the given proteins on the gel concentration (% T), see **Figure 3**. The slope of this dependence, the retardation factor,  $K_R$ , is linearly related to the molecular radius or  $M_r$ .

**PAGE in the presence of sodium dodecyl sulfate (SDS)** Most proteins bind the anionic detergent SDS in a constant mass ratio, 1.4 g of SDS per gram of protein, effectively masking the intrinsic charge of the protein. Consequently, the charge-to-mass ratio of almost all protein-SDS complexes is constant, their mobilities in a free solution are identical, and they can be electrophoretically separated only in

**Figure 3** Ferguson plot of bovine  $\gamma$ -crystallin proteins. Four different gel concentrations (5.0%, 6.25%, 7.3%, 8.3% T) with Tris-glycine gel buffer were used for determination of the slope,  $K_R$ , of each subfraction, which is proportional to the relative molecular mass,  $M_r$ , of the native protein. (Reprinted with permission from Chiou SH and Wu SH (1999) Evaluation of commonly used electrophoretic methods for the analysis of proteins and peptides and their application to biotechnology. *Analytica Chimica Acta* 383: 47–60; © Elsevier.)

media exhibiting the sieving effect. In addition to masking of protein intrinsic charge, the detergent SDS molecules cause unfolding and denaturation of proteins by disruption of hydrogen bonds. Thus SDS-PAGE is characterized as denaturing electrophoresis, unlike the native electrophoresis described above. For complete denaturation and unfolding of proteins, the intra- and interchain disulfide bonds between cysteine residues are cleaved by reduction with mercaptoethanol or dithiothreitol, and the free -SH groups are protected by alkylation with iodoacetamide. There are two main buffer systems used for SDS-PAGE, the continuous phosphate buffer suggested by Weber and Osborn and the discontinuous system of Laemmli, which is in fact the original Ornstein-Davis native discontinuous Tris-HCl/Tris-glycine buffer system in the presence of SDS.

Due to a number of advantages, SDS-PAGE has become one of the most widely applied techniques for analysis and characterization of proteins. SDS solubilizes almost all proteins, and SDS-protein complexes are uniformly and highly negatively charged, i.e., fast migrating in the same anodic direction. In addition, SDS-protein complexes are better fixed and

stained in the strongly restrictive gels than are native proteins. Separation is based on a physicochemical parameter, the effective molecular radius. In gels with uniform concentration, there is a linear relationship between the relative mobility ( $R_f$ ) and  $\log_{10} M_r$  of the SDS–polypeptide complex. From this linear dependence (calibration curve of a given gel) the  $M_r$  values of investigated proteins can be read. However, the linear relationship between  $\log_{10} M_r$  and  $R_f$  is valid only over a limited range of molecular mass; e.g., linearity in the  $M_r$  range 14 000–95 000 is achieved in a 5% T stacking gel and 14% T resolving gel. Moreover, some glycoproteins, collagenous polypeptides, and some very basic or acidic proteins behave anomalously, providing false  $M_r$  values.

### IEF in Agarose or PAA Gels

IEF is in fact electrophoresis of amphoteric molecules (proteins and peptides) in an electrolyte system with a pH gradient. In this pH gradient proteins move according to their charge until they reach the region of pH at which their effective charge is zero, i.e., their isoelectric point (pI).

**IEF with carrier ampholytes** In classical IEF the pH gradient is created and maintained by the passage of electric current through a solution of complex mixtures of small synthetic amphoteric molecules with closely spanned isoelectric points due to different amounts and ratios of both basic amino- and acidic carboxylic groups. These carrier ampholytes are electrophoretically transported according to their pI and thus form the pH gradient with the pH increasing from the anode to the cathode. The widest pH range of IEF with carrier ampholytes is 3.5–10. Unlike ZE, IEF is a steady-state technique, i.e., once the proteins have reached their pI, they remain concentrated (focused) in narrow zones at the pH equal to their pI. Because of the focusing effect of the pH gradient, sharp protein zones with high resolution (pI difference up to 0.01) can be obtained. In gel IEF it is important to use gels with a large porosity; in a low concentration (3–5% T) PAA gel proteins with  $M_r$  up to 750 000 can be separated, but for proteins with  $M_r > 500\,000$ , agarose gels (0.8–1.0%) are preferred. The solubility of hydrophobic and other low-solubility proteins, which is lowest at pI, can be improved by addition of chaotropic agents, urea or thiourea, and nonionic (Triton X100) or zwitterionic (CHAPS) detergents.

**IEF with immobilized pH gradient** An important innovation in IEF was the development of special reagents (immobilines) for preparation of PAA gels

**Figure 4** High resolution IEF of proteins from potatoes of different varieties in slab PAA gel with carrier ampholytes. Staining with CBB. (Reproduced with permission from Westermeier R (1997) *Electrophoresis in Practice: A Guide to Methods and Applications of DNA and Protein Separations*. Weinheim: Wiley-VCH; © Wiley-VCH.)

with immobilized pH gradients (IPGs). The pH gradient is prepared before the IEF run by copolymerization of several acrylamide derivatives containing either an acidic carboxylic group or basic tertiary amino groups. Depending on the amounts and ratio of acidic and basic acrylamide derivatives in the polymerization mixture in different places of the gel matrix, a PAA gel with different acidity (pH gradient) is formed. The main advantage of IPGs is that the buffering groups forming the pH gradient are covalently attached and immobilized to the PAA backbone. The pH gradient they generate is also immobilized and stable in time and space, eliminating the deleterious effects of pH gradient (cathodic) drift commonly observed in conventional IEF with carrier ampholytes.

IEF in horizontal slab gels of ultrathin thickness (0.05–0.5 mm) cast on thin plastic supports with improved heat transfer is largely applied to protein analysis, preparation, and characterization. It is used for determination of isoelectric points of proteins, for evaluation of protein microheterogeneity, for identification of genetic variations (see Figure 4), and for investigating chemical, physical, and biological influences on proteins. One of the most important applications of IEF is using this technique as the first dimension separation of two-dimensional (2D) gel electrophoresis.

### 2D-PAGE

The separation power of 1D electrophoretic or other separation techniques for analysis of complex protein mixtures is rather limited since closely related proteins remain unresolved in overlapping zones. The

**Figure 5** Principle of high resolution 2D gel electrophoresis. (Reproduced with permission from Westermeier R (1997) *Electrophoresis in Practice: A Guide to Methods and Applications of DNA and Protein Separations*. Weinheim: Wiley-VCH; © Wiley-VCH.)

principle of solution of this problem is to combine two independent separation principles based on two different physicochemical parameters in one method. This was performed in 1975 by O'Farrell, who combined the high resolving power of IEF, separating proteins according to isoelectric points, with the high-resolution SDS-PAGE, separating proteins according to size, and developed 2D-PAGE, which can resolve up to a few thousand proteins.

In the first step the sample is dissolved in a small volume of a denaturing solution containing urea, nonionogenic or zwitterionic detergents, and a reducing agent (dithiothreitol). This sample buffer solution can dissolve and dissociate most proteins without changing their intrinsic charge. The dissolved polypeptide mixture is separated by IEF as described above. In the second step the thin (0.5–1 mm) rod-like or strip gel containing the IEF separated proteins is soaked in SDS-containing buffer (see Figure 5) and the protein–SDS complexes are separated in the second dimension in the slab gel according to size in the SDS-PAGE mode. The result of separation is a pattern of spots of stained proteins in a rectangular area – the 2D protein map.

The separation parameter of the first dimension (pI) is independent of  $M_r$ , which is the separation parameter of the second dimension. Consequently, the 2D IEF  $\times$  SDS-PAGE separation is orthogonal and able to provide the highest resolution of complex protein mixtures, such as proteins of biofluids, cell lysates, and tissue extracts, among all currently available methods. Under optimized separation conditions, with large-size gels, sensitive silver staining, or autoradiography detection, quite a few thousand proteins can be resolved and detected in one

**Figure 6** 2D gel electrophoresis of liver proteins. Approximately 40  $\mu$ g of protein was separated using IEF on pH 5–8 IPG strips for 22 000 V h followed by a second dimension SDS-PAGE on a 12% T PAA gel and was silver stained. (Reproduced with permission from Yarmush ML and Jayaraman A (2002) *Advances in proteomic technologies. Annual Review of Biomedical Engineering* 4: 349–373.)

two-dimensional electrophoresis (2-DE) map (see Figure 6). Naturally, 2-DE has become a basic technology in proteomics.

The high reproducibility of the positions of the spots, which is very important for interpretation of protein 2-DE maps, has been particularly improved with IPGs used in the first, IEF, dimension. For qualitative and quantitative analysis and for intergel comparison the 2-DE maps are converted into digital data using densitometers, scanners, or video cameras and evaluated by computer image analysis.

## Detection

Proteins separated in gels are mostly detected using staining techniques based on the ability of different dyes to form colored complexes with proteins and to visualize them. Coomassie brilliant blue (CBB) is the most commonly used organic stain for detection of proteins in gels. The relatively high staining intensity of Coomassie blue stains is based on the electrostatic interaction between the dye molecules and the amino groups of proteins and, on the secondary bonds, dye-dye interactions between the dye molecules. CBB, in a micellar form, can detect as little as  $\sim 50$  ng of protein and gives a linear response in the densitogram of up to  $20\ \mu\text{g}$ , but the slope of the response is different for different proteins. The sensitivity of detection and resolution of the separation is increased by fixing proteins in gel with trichloroacetic acid. Amido black and fast green are other organic dyes used for protein detection, but their sensitivity is three to six times lower than that of CBB.

More than a hundred times higher detection sensitivity, up to  $0.1$  ng of protein, is achieved by silver staining. It is based on reduction of silver ions to metallic silver due to differences in the reduction-oxidation potential between the sites occupied by proteins and the adjacent sites of the gel or membrane. Densitograms of silver-stained protein electrophoregrams are linear over a 30- to 40-fold range for most proteins, but the slope of the response also differs for different proteins.

The other techniques used for protein detection in gels include direct ultraviolet (UV) densitometry, and autoradiography and fluorography of radio- or fluoro-labelled proteins, respectively. Methods have also been developed for identification of specific types of proteins. Proteins may be stained on the basis of the presence of specific moieties (e.g., glycoproteins) or by their specific enzymatic activity (positive or negative zymograms). Immunochemical methods are used for identification of proteins with specific antigenic sites (e.g., allergens, phosphoproteins).

Both universal staining procedures and specific detection techniques can be performed after (electro) transfer or (electro)blotting of proteins (also called Western blotting) from the gel matrix (which sometimes hinders protein analysis) to a nitrocellulose or polyvinylidenedifluoride membrane, to which they are bound and immobilized. On the membrane, protein molecules are faster and better accessible for the interactions with the applied specific antibodies. The antigen-antibody complexes are visualized by a second antibody (against the first antibody) with an attached enzyme label, which catalyzes the color reaction in the place of the protein zone.

In the latest developments, matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) has been employed for detection of proteins with the capability to determine their  $M_r$  with high accuracy.

## Capillary Electrophoresis

### Basic Characteristics, Advantages, and Problems Encountered

Since the 1980s electromigration methods have started to be performed in thin-wall microbore fused silica capillaries with a typical i.d. of  $25\text{--}75\ \mu\text{m}$  and length  $20\text{--}70$  cm. The capillary format of the separation compartment brings significant advantages over gel electrophoresis.

1. Capillaries possess a stabilizing anticonvective effect, allowing separation in a free solution, under mild conditions, preserving the biological activity of biomolecules.
2. The relatively high surface/volume ratio of the separation compartment ensures efficient Joule heat transfer from the separation space, which allows application of high-intensity electric fields, up to  $1000\ \text{V cm}^{-1}$ , resulting in fast and highly efficient separations of analytes.
3. Online, on-column, or end-column detection makes possible direct monitoring and evaluation of the separation process; the whole analytical procedure can be automated.

During the last decades the different modes of capillary electrophoresis (CE) have developed into high-performance (HPCE) separation methods, offering a high separation efficiency ( $10^5\text{--}10^7$  theoretical plates), high sensitivity (femtomole to zeptomole amounts in nano- to picoliter sample volumes), and short analysis times (typically  $5\text{--}20$  min, in special cases only a few seconds). They are considered as a recognized complement and/or counterpart of liquid chromatography (LC) and gel electrophoretic methods.

The application potential of HPCE methods is extremely large; they can be used for separation of any class of compounds, ionogenic and nonionogenic, small ions and macromolecules, and also for (bio)particles and cells. Proteins belong to the substances most frequently analyzed using HPCE.

CE is mostly performed in fused silica (FS) capillaries, which form a suitable separation compartment because of their reproducible physical dimensions, good electrical isolation properties, high thermal conductivity, and transparency in the short wavelength UV radiation used for detection. However, the dissociation of silanol groups created on a

hydrated FS surface brings complications for CE separation of proteins due to their adsorption to the ionized capillary wall. There are several strategies for suppressing protein adsorption to the FS capillary. In addition to the separations performed in extreme (high or low) pH and high ionic strength BGEs, different FS capillary coatings are employed. Dynamic coatings result from reversible (dynamic) adsorption of either low molecular mass compounds (alkylammonium cations, amines) or hydrophilic polymers such as cellulose derivatives added to the BGE. Static (permanent) modification of the capillary wall is carried out prior to filling the capillary with BGE and may involve the formation of a covalent bond between a suitable derivatized coating agent and the silanol groups of the silica, giving rise to an immobilized polymeric coating, or the bond may be noncovalent but yet 'permanent', resulting from the irreversible adsorption of the polymer, e.g., poly(vinyl alcohol) or poly(ethylene glycol), to the capillary wall.

The second important phenomenon induced by the dissociation of silanols is the electroosmotic flow (EOF), i.e., bulk flow of BGE inside the capillary resulting from application of an electric field on a free charge in the diffusion part of the electric double layer close to the capillary wall. The EOF in the bare FS capillary has a cathodic direction, and its velocity

is higher than the electrophoretic velocity of proteins, which allows analyzing both positively and negatively charged proteins in a single experiment.

### Separation Modes

In the capillary format, different electromigration separation principles (separation modes) are performed.

*Capillary zone electrophoresis (CZE)* is the simplest and most universal CE mode applied to separation of proteins. Separation takes place in the homogeneous solution of the background electrolyte (BGE) on the basis of different electrophoretic mobilities of analytes in a free solution. Sample components are separated into zones with gaussian concentration profiles. The selectivity of protein separations is manipulated mainly by changes in their charge-to-size ratio, which can be achieved by changes in the composition, pH, ionic strength, viscosity, permittivity, and temperature of the BGE. The high resolving power of CZE is demonstrated in **Figure 7**, showing the separation of human growth hormone (hGH) and its deamidation products, differing in one elementary charge per 191 amino acid residues. CZE in sieving media, particularly in replaceable solutions of entangled polymer networks (linear PAA, dextran), is broadly applied for SDS-electrophoresis of proteins.

**Figure 7** CZE separation of hGH and its derivatives. CZE performed in FS capillary (i.d. 50  $\mu\text{m}$ , total length 105 cm, effective length (to detector) 81.5 cm; BGE: 10  $\text{mmol l}^{-1}$  Tricine, 5.8  $\text{mmol l}^{-1}$  morpholine, 20  $\text{mmol l}^{-1}$  NaCl, pH 8.0; electric field intensity 300  $\text{V cm}^{-1}$ , current 20  $\mu\text{A}$ , temperature 24°C. 1, hGH; 2, (desamido-149)- and (desamido-152)-hGH; 3, (didesamido-149-152)-hGH. Mesityl oxide, electroosmotic flow marker. (Reprinted with permission from Grossman PD, Colburn JC, Lauer HH, *et al.* (1989) Application of free-solution capillary electrophoresis to the analytical scale separation of proteins and peptides. *Analytical Chemistry* 61(11): 1186–1194; © American Chemical Society.)

*Capillary ITP (CITP)* is suitable for determination of low molecular mass ionic admixtures of proteins, and it is also often used as a preconcentration and/or preseparation step prior to CE analysis of proteins present at low concentrations and/or in complex mixtures, increasing the sensitivity up to several hundred times.

*Capillary IEF (CIEF)* combines the high resolving power of conventional gel IEF with the advantages of CE instrumentation. The capillary format with efficient Joule heat transfer permits the application of high electric field strengths for rapid and high resolution focusing with online detection of separated zones mobilized by EOF, electroelution or hydrodynamic flow. CIEF is used for investigation of protein microheterogeneity and for pI determination. Due to its focusing effect, CIEF is frequently used as the first concentrating step in 2D or multidimensional separations of complex protein mixtures. A 2D separation, analogous to classical IEF/SDS-PAGE, is achieved by a combination of CIEF with mass spectrometric detection, which also provides both pI and  $M_r$  values.

*Capillary (bio)affinity electrophoresis* is mostly used as a mild and sensitive tool for the investigation of interactions of proteins with other molecules and for estimation of the binding constant of their complexes.

*Capillary electrokinetic chromatography* with micellar pseudophases of ionogenic detergents, anionic SDS, or cationic cetyltrimethylammonium bromide, is capable of resolving small proteins or polypeptides ( $M_r < 6500$ ) with minor differences in hydrophobicity resulting, e.g., from replacement of a single nonionogenic amino acid by other electroneutral amino acid residue.

## Detection

One of the main advantages of CE over gel electrophoresis is that the separation is monitored by online, on-column, or end-column detection. In the most frequently employed UV absorption photometric detection, a small part (less than 1 mm) of the capillary serves as a detection cell. Micromolar concentrations of proteins are detectable using the low UV detection wavelength of 200–220 nm. A higher sensitivity, up to nanomolar concentrations, is achieved with fluorescence, particularly laser induced fluorescence (LIF) detection. The disadvantage of the LIF detection of proteins is the necessity for their derivatization using a fluorogenic label. The native fluorescence of proteins, mostly due to the presence of aromatic amino acids residues, tryptophan, and tyrosine, can be utilized only when low UV laser

systems with an excitation wavelength between 270 and 300 nm are available or when two or three visible or infrared photon excitation is possible.

Mass spectrometry (MS) is, due its universality, sensitivity, and selectivity, the most powerful detection principle for CE. The introduction of electrospray ionization (ESI) and MALDI have especially brought tremendous progress in online and offline characterization of proteins separated electrophoretically using MS. A combination of CE with ESI-MS and MALDI-MS allows not only high accuracy determination of the protein  $M_r$  but also provides important structural data on amino acid sequences, posttranslational modifications, peptide mapping, and noncovalent interactions of proteins. The MS detection principle, combined with the high resolution of CE, is becoming of importance, namely for comprehensive analysis of proteins (proteomics) and for protein characterization by peptide mapping.

## Separation on Microchips

Electrophoretic techniques performed on microfabricated devices – microchips – represent the platform for a new generation of miniaturized analyzers where all operations, sample introduction, derivatization, separation, and detection are fully integrated and automated in the so called ‘micro-total analytical systems’ or ‘labs on a chip’. They are expected to become the most powerful tools of analytical chemistry in the coming period, with broad application in life sciences, particularly proteomics, requiring fast, highly efficient, highly sensitive, and high throughput separation and characterization of complex protein mixtures.

## Applications

Both gel electrophoresis (GE) and CE have an extremely broad application potential for analysis, preparation, and characterization of proteins.

## Analysis

There are thousands of applications of both GE and CE for qualitative and quantitative analysis, quality control, or purity determination of proteins isolated from the natural material or prepared using modern recombinant DNA technology, for monitoring the modification of proteins through chemical reactions or enzymatic conversions, for amino acid and sequence analysis of proteins, and for protein characterization by peptide mapping. Only a few of them will be mentioned here as illustrative examples.

Validated CE and GE methods have been developed for the qualitative and quantitative analysis of

biotechnologically produced protein pharmaceuticals, such as human insulin, growth hormone, tumor necrosis factor, antithrombin III, hirudin, and many others.

The high sensitivity of GE and CE, frequently in combination with online sample cleanup and pre-concentration, allows these methods to be applied to the analysis of proteins present at low concentration levels in complex biomatrices, such as biological fluids (blood, serum, plasma, urine, cerebrospinal fluid), cell lysates, and tissue extracts. Protein biomarkers of physiologically important processes and diseases, such as abnormal prion proteins in the blood of animals and humans infected with a transmissible spongiform encephalopathy,  $\beta$ -amyloid polypeptides in plasma or serum of Alzheimer disease patients, peptidomimetic inhibitors of HIV-1 protease in serum of AIDS patients were determined using CZE. Both GE and CE (CITP) are applied for analysis of lipoproteins and apolipoproteins in plasma and for elucidation of disorders of lipoprotein metabolism related to diseases of the cardiovascular and central nervous systems. Slab gel IEF of proteins, particularly some enzymes, is used for blood group typing in the medico-legal field.

In addition to analysis of 'static' protein preparations, GE and CE are capable of also monitoring dynamic changes in proteins, such as their chemical modifications and reactions (oxidation, reduction, deamidation, hydrolysis), physical changes (denaturation, aggregation, folding/unfolding), and enzymatic conversions, including physiologically important posttranslation modifications as phosphorylation and glycosylation. Several CE applications deal with enzymatic conversions of proteins for studying some details of these processes and/or activities of enzymes and the kinetics of their action on proteins and peptides. An example of CZE monitoring of pig insulin cleavage using trypsin is shown in Figure 8. Another application is CZE monitoring of asparagine deamidation and aspartate isomerization in recombinant human interleukin-11 due to heat stress and determination of activity of angiotensin-converting enzyme, an important regulator of blood pressure.

The high separation power makes CE and GE powerful techniques for peptide mapping, i.e., separation of peptide fragments originating from specific chemical and/or enzymatic hydrolysis of proteins and polypeptides. Peptide mapping serves as an important tool for protein identification, for sequence determination of internal parts of polypeptide chains, for monitoring of posttranslational modifications, and elucidation of the structure of proteins. Due to the high complexity of peptide maps, namely of large proteins, usually multidimensional separations,

**Figure 8** CZE analysis of pig insulin (A) and monitoring the cleavage of pig insulin using trypsin after 7, 20, 40, and 60 min (B–E). 150  $\mu$ g of pig insulin dissolved in 150  $\mu$ l of BGE and mixed with 50  $\mu$ g of trypsin dissolved in 100  $\mu$ l BGE and analyzed at given time periods using CZE in a FS capillary (i.d. 56  $\mu$ m, total/effective length 31/20 cm; BGE: 10 mmol l<sup>-1</sup> tricine, 5.8 mmol l<sup>-1</sup> morpholine, 20 mmol l<sup>-1</sup> NaCl, pH 8.0; voltage 7.3 kV, current 20.0  $\mu$ A; UV absorption detection at 206 nm. PI, pig insulin; DOI, des-octapeptide-B23-30-insulin; NA, nicotinamide (EOF marker). (Adapted from Kašička V (1999) Analytical and preparative separations of peptides by capillary and free-flow zone electrophoresis. In: Aboul-Enein HY (ed.) *Analytical and Preparative Separation Methods of Biomacromolecules*, pp. 39–97. New York: Dekker.)

2D-PAGE or CE-MS, are necessary for complete resolution of these mixtures. CE separation of tryptic peptides of hemoglobins, i.e., peptides obtained by cleavage of hemoglobin by trypsin, allows identification of hemoglobin variants in clinical laboratories. The comparison of CZE and LC tryptic peptide maps of hGH presented in Figure 9 demonstrates the high separation power and complementarity of reverse-phase (RP) LC and CZE, the latter however being four times faster.

### Preparative Separations

Several special apparatus have been designed for large-scale electrophoretic separation of proteins, but none of them is widely used nowadays. The main reason is that the Joule heat produced in the enlarged separation compartment cannot be sufficiently and evenly dissipated, which results in a high temperature increase and a temperature gradient in the separation compartment and loss of separation power. A

**Figure 9** Comparison of RP-LC (A) and CZE (B) separations of tryptic peptides of hGH. Peak assignments and correlations for selected fragments are noted. CZE: background electrolyte  $0.01 \text{ mol l}^{-1}$  Tricine,  $0.045 \text{ mol l}^{-1}$  morpholine,  $0.02 \text{ mol l}^{-1}$  NaCl, pH 8.0, detection at 200 nm, 316 V cm,  $20 \mu\text{A}$ . LC: column Aquapore RP-300 ( $4.6 \times 250 \text{ mm}$ ), flow rate  $1 \text{ ml min}^{-1}$ , detection 214 nm. Solvents: A, 0.1% trifluoroacetic acid (TFA) in water; B, 0.1% in acetonitrile; gradient 0–20% B in 20 min, 20–25% B in 25 min. (Reprinted with permission from Grossman PD, Colburn JC, Lauer HH, *et al.* (1989) Application of free-solution capillary electrophoresis to the analytical scale separation of proteins and peptides. *Analytical Chemistry* 61(11): 1186–1194; © American Chemical Society.)

compromise between the deleterious effects of Joule heating and the preparative capacity is best achieved in column electrophoresis with an annular geometry with subsequent elution of the separated proteins after they leave the gel.

Due to the inherently low preparative capacity of miniaturized thin layer gels and capillary columns, the application of GE and CE for preparative separations of proteins is limited to cases where their nanogram to microgram amounts are sufficient for further characterization, e.g., using offline MS or using amino acid and sequence analysis. A higher preparative capacity (50–100 mg of proteins per hour) is obtained in free-flow electrophoresis. In this technique the sample is continuously introduced into the laminar flowing thin layer of the BGE in the rectangular flow-through electrophoretic chamber. During the flow-through time the sample components are separated according to their electrophoretic mobilities using an electric field oriented perpendicular to the hydrodynamic flow of the BGE and the sample solution.

### Physicochemical Characterization

GE and CE can also provide important physicochemical characteristics of the separated proteins, such as effective and absolute (limiting) mobilities, effective charges, isoelectric points, relative molecular masses, Stokes radii, acid–base dissociation constants of ionogenic groups, diffusion coefficients, association (dissociation) constants of protein complexes, and rates of protein physical changes and chemical reactions. The size parameters (diameter or  $M_r$ ) of proteins are obtained from CE and GE in sieving media; the effective charge of proteins may be estimated from separation of protein charge ladders; the  $pK_a$  values of ionogenic groups of proteins are determined from CZE measurements of the dependence of the effective mobility on the pH; the pH dependence of proteins' effective mobility and the isoelectric point can be obtained using a special 2D technique, the electrophoretic titration curve, based on the application of protein(s) as the longitudinal zone in the middle of slab gel along the pH gradient, first formed by IEF in one direction, followed by protein electromigration in the direction perpendicular to the direction of the pH gradient. The diffusion coefficients of proteins can be estimated from their 'stopped flow' CZE separations. CE and GE separation of folded and unfolded forms of proteins and polypeptides allows us to study the equilibria and kinetics of conformation transition states during

protein and polypeptide folding–unfolding processes and coil–helix transitions.

### Chemical Speciation: Concept and Importance

Analytical information about the total amount of trace and ultratrace level concentrations of elements is increasingly demanded in biology, medicine, industry, and environment. The interest in trace and ultratrace elements in living organisms began after discovering the presence of various metals in a number of bio-compounds having biological significance. Moreover, it was demonstrated that trace and ultratrace elements in a living organism could play important roles including: (1) 'Essential' element: the simplest definition is an element required for life in such a way that their absence results in death or severe malfunction of the organism. The relationship between concentration level of an essential element and biological function is shown in **Figure 1**. (2) 'Toxic' element: as can also be seen in **Figure 1**, they are elements that can be harmful or even lethal at very low concentrations. As a toxic element concentration increases, its deleterious effect becomes more harmful. (3) 'Therapeutic' element: an element that can be beneficial to health when administered at higher levels than those of essential elements (see **Figure 1**).

However, metals and semimetals naturally occur in many physicochemical forms or species in the different environmental compartments. They may be found as free metal ions, hydroxides, organometallic compounds, large biomolecules, etc. In fact, today it

is worldwide recognized that the actual distribution, mobility, bioavailability, toxicity, bioaccumulation, and biodegradability of an element will depend not only on its total concentration but on its chemical form in the sample. Therefore, total concentration determinations of an element seem to provide incomplete information on its mobility, ecotoxicity, bioavailability, etc. For this reason the analysis of its physicochemical form(s) then becomes mandatory to understand its biological behavior, its toxicity, or its eventual environmental impact.

A simple and well-known example of speciation importance is arsenic present in marine foodstuffs. Inorganic arsenic species have long been recognized to be highly toxic. However, the major arsenic compound content in such food turns out to be arsenobetaine or arsenosugars, which are totally harmless to humans (as they are not metabolized during digestion). Similarly, all forms of mercury are toxic but their toxicity depends strongly on the metal

**Figure 1** Concentration levels of essential, toxic, and therapeutic elements and their influence on health.

chemical form: methylmercury (MeHg) is one of the most toxic species and the famous Minamata Bay disaster in the 1950s was caused by MeHg poisoning. An industrial effluent forming MeHg was discharged in the Minamata Bay being then bioconcentrated by the fish. Not only animals (e.g., cats) but also humans were severely affected by consumption of the contaminated fish. Thus, MeHg was the origin of the so-called 'Minamata disaster', as the toxicity of the methylated mercury compound (e.g., to the central nervous system) turned out to be much stronger than that of inorganic mercury.

These two examples have been selected only to illustrate the fact that elemental speciation information is today urgently needed as total determination can be even misleading.

According to IUPAC recommendations a 'chemical species' is the specific form of an element defined as to isotopic composition, electronic or oxidation state, and/or complex of molecular structure. 'Speciation analyses' are the analytical activities of identifying and/or measuring the quantities of one or more individual chemical species in a sample, while 'speciation of an element' is the distribution of an element amongst defined chemical species in a system.

Although metal speciation began closely related to the toxicity aspects and to environmental concerns, speciation information is increasingly demanded from most varied areas. The main fields for speciation analysis today are: environment, biology, and medicine, and also industrial analysis. Environmental monitoring (air, water, soils, sediments, and biota) of anthropogenic organometallic contaminants (e.g., organolead or organotin) and of toxic redox states (e.g., Cr(III) is essential while Cr(VI) is carcinogenic) is one of the better established speciation fields. Elucidation of biomethylation metal mechanisms, as methylated compounds show different toxicities than the inorganic forms (e.g., Hg, As, Se), is another important area of chemical speciation activity.

In biology and medicine, identification and characterization of species of essential (e.g., Fe, Cu, Zn, Se), toxic (e.g., Hg, Pb, Cd, As), and therapeutic elements (e.g., Pt, Au) in living organisms is arousing great interest these days. Also, in occupational medicine, speciation provides information about the volatile species (e.g., Hg) and inhalable particles at the workplace (e.g., Cr(VI) in dust particles), providing information about trace element toxicants' absorption, distribution, reactivity, toxicity, and the final excretion after an occupational exposure to Pb, Cr, As, etc.

Distribution, transport, metabolism, and detoxification studies of both essential and toxic trace elements via speciation information are becoming popular in ecotoxicology as well.

On the other hand, the importance of trace element speciation is also increasing so as to help understand the bioavailability of inorganic nutrients (Fe, Cu, Zn, Se) from food. Of course, intelligent administration of food supplements (e.g., the assimilation of selenium in living organisms and its metabolic processes closely depend on Se chemical form) demands more and more information on the actual species present in the supplement.

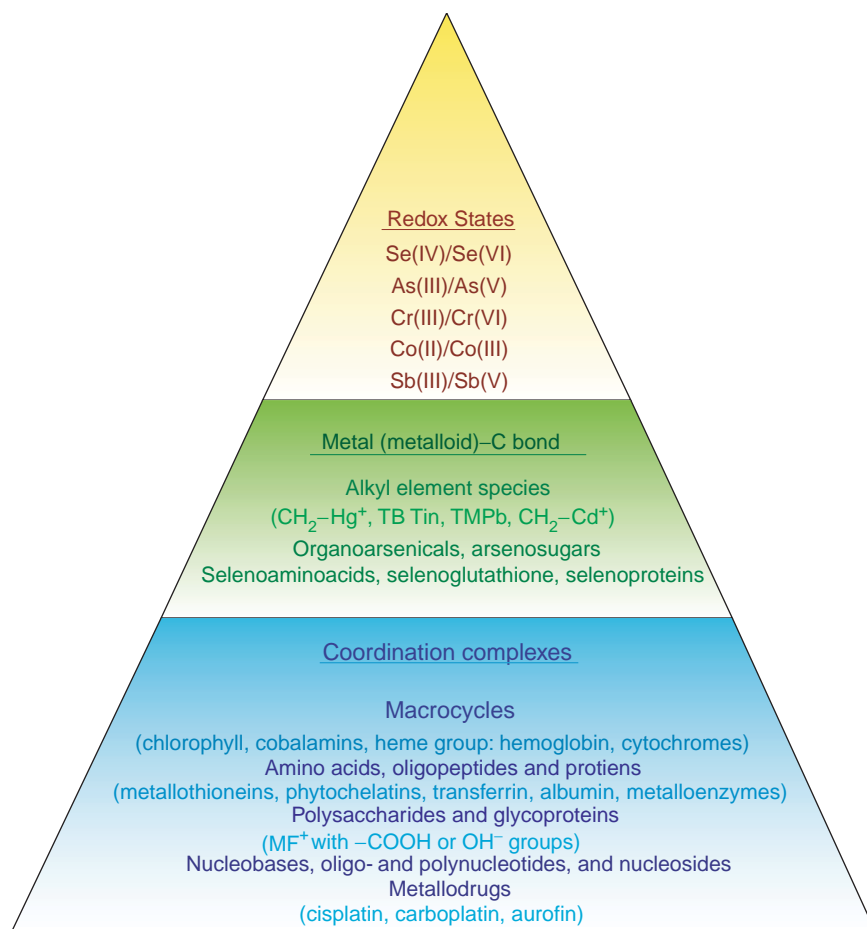

Finally, metal species analysis is becoming of great practical importance in industrial processes. Some examples are food industry speciation studies, required for determining actual toxicity of contaminated foodstuff (e.g., fish by methylmercury, oysters and mussels by organotin or arsenic, or wine by organolead). In the petrochemical industry speciation of Fe, V, Co, or Ni geometalloporphyrins of crude oil is increasingly demanded. Also, in the pharmaceutical industry and in the production of packing materials, speciation and speciation analysis become increasingly important (e.g., organometallic compounds can be used as catalysts or polymer stabilizers like tributyltin (TBT), etc.).

In brief, as shown in Figure 2, analytes or compounds of interest in speciation analysis are becoming important in many fields. They include redox states, organometallic compounds (with a strong metal-carbon covalent bond), and also coordination complexes with any kind of ligands including small compounds (e.g., in metallodrugs) and big metal-biomolecules (formed in the living organisms as a result of the metabolism of the element, e.g., Cd-metallothioneins).

## The Analytical Challenge of Trace Element Speciation

As speciation information is becoming very important, analytical methods and strategies to obtain such information are urgently needed and are now being widely developed.

However, trace element speciation analyses constitute a real challenge for present analytical chemistry, due to their complexity, which stems from the following aspects: (1) The first problem is related to the 'lability' of the target species: changing the ambient conditions from those prevailing in the original systems may often disturb the existing physicochemical equilibria and so the resulting speciation information may not be fully representative of that originally present in the sample. (2) Sensitive and selective detectors are required to measure the extremely low concentrations, naturally found in the real-life samples. This is

**Figure 2** Typical analytes sought in speciation analysis.

particularly difficult after the fractionation of the different metal forms needed for speciation. Of course, except for highly contaminated samples, speciation of toxic metals is even more difficult because their content is usually at micrograms per liter levels or below. (3) The trace amounts of the species sought are 'buried' in a very complex matrix (e.g., serum, sediment, soft tissue, etc.).

According to the chemical nature of the species to be analyzed, three different categories of speciation analysis have been proposed:

- Category I. Thermodynamically stable and kinetically inert species (e.g., organometallics such as MeHg, TBT, selenoproteins, and Se-aminoacids).
- Category II. Thermodynamically stable but kinetically labile or dynamic species. That is, compounds or species having a relatively high stability constant in solution (e.g., Al-transferrin, Cd-metlothionein, oxidation states), which have to be carefully preserved in order to prevent their alterations (reaction).
- Category III. Weakly bound and dynamic species like the so-called 'labile-monomeric aluminum', present in natural water (e.g., Al<sup>3+</sup>, Al(OH)<sup>2+</sup>, Al(OH)<sup>+</sup>, AlCl<sup>2+</sup>, etc.), which are, in fact, a group of chemical species instead of a defined one. All of them behave in a 'group-similar' manner that can provide useful information (e.g., 'labile monomeric aluminum' for the toxicity of acidified waters to fish).

Most of methods developed for analytical speciation involve several steps: species extraction, preconcentration, cleaning, derivatization, separation, and detection. Such process could affect the integrity of the species sought. Of course, accurate speciation analysis requires preserving the integrity of the species sought along the whole analytical process, from sampling to final measurement. Since species lability increases from Category I to III, the analytical requirements needed to preserve the integrity of the analyte (species) increases in the same order.

## Analytical Strategies and Techniques

A large number of analytical techniques and strategies have been developed to tackle modern speciation problems. There are four main approaches possible: computational, direct species-specific detection, hybrid techniques, and physicochemical characterization techniques.

### Computational Approach

This theoretical approach consists of numerical thermodynamic calculations of the species present in the sample. Knowing the pH, ligand and metal concentrations, temperature, redox potential, and formation constants, it is possible to predict the speciation of an element in a given sample. This approach, however, has several limitations because in most cases we do not know all the ligands' concentrations or the thermodynamic constant values. What it is more, kinetic aspects are not considered in such models, the system is usually considered to be homogeneous.

Notwithstanding the above constraints, computational methods are useful for a first approximation for a speciation problem or to predict speciation changes caused by changes in a parameter of the environmental conditions. Published practical examples of speciation by using a computational approach are the aluminum speciation in serum and distribution of trace elements in fresh waters.

### Direct Species-Specific Techniques

The direct species-specific techniques would be the ideal speciation procedure, providing identification and quantification of a given individual species *in situ* without any sample treatment. The techniques of this type, more used for individual metal-containing species determination, are electroanalytical in nature (e.g., ion-selective electrodes have been used for determining major free alkali ion determinations in natural waters and serum). More sensitive voltamperometric redissolution techniques can be useful for speciation of free and 'labile' forms of metals (or their different oxidation states) in waters.

In general, electrochemical techniques lack the required selectivity to be used for most ultratrace and trace element levels present in complex real samples (e.g., environmental and biological matrices).

Molecular techniques based on ultraviolet (UV)–visible spectrophotometry and fluorimetry have been also proposed for direct determination of a specific element form. Colored species, such as those of Cr or Mn, can be directly determined spectrophotometrically. However, most of such species will require the use of a selective color-forming reagent, lacking the sensitivity, and often the selectivity, required for

speciation analysis. More recently, investigations are directed to develop the analytical potential of biosensors that could be adequate for *in situ* monitoring of species without sample disturbance.

## Hyphenated Techniques and Selected Speciation Examples

Without discussion, the tools most commonly used for trace element speciation analysis nowadays are 'hyphenated techniques', which is the coupling of more than one technique: one or more of them facilitating the separation of the various forms of the element of interest and the other for the final sensitive and selective detection of the element. The main separation methods and detectors commonly used in hyphenated or coupled techniques for speciation analysis have been summarized in Figure 3. These species separation techniques can be coupled online or offline with the detector (usually an atomic spectroscopic detector).

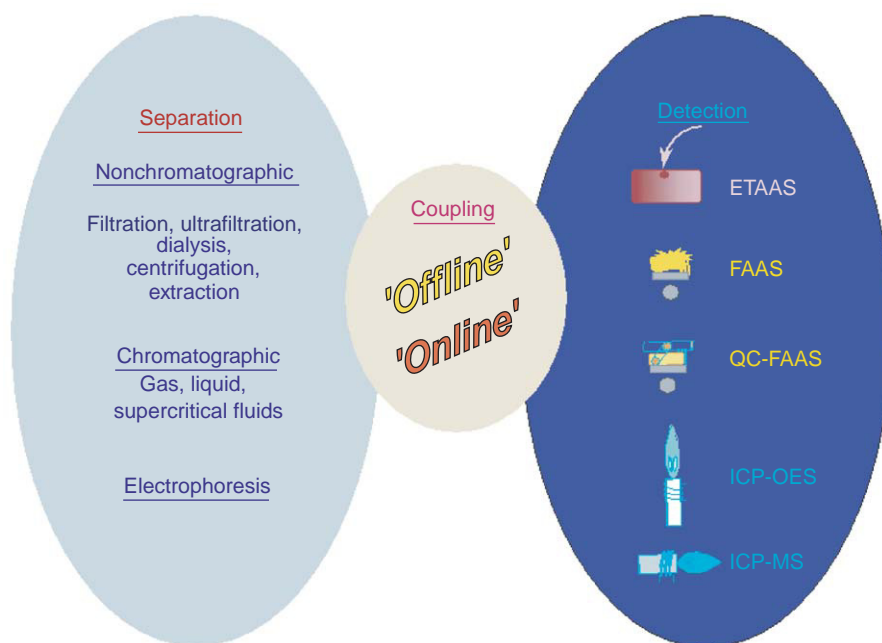

### Speciation by 'Offline' Couplings

Notwithstanding the fact that a continuous or 'online' coupling is desirable for speciation purposes, there are examples of the usefulness of both discontinuous nonchromatographic (e.g., ultrafiltration) and continuous separation techniques (e.g., chromatography), which have been coupled offline with atomic detectors to solve important problems requiring speciated information.

An interesting illustrative example of 'offline' speciation usefulness is aluminum speciation in human serum. Aluminum has been shown to be very toxic to renal failure patients suffering long-term hemodialysis. Ultrafiltration using 30 kDa membranes and electrothermal atomic absorption spectrometry (ETAAS) detection was employed to demonstrate that ~90% of Al in human serum is bound to proteins. Therefore, only 10% of serum aluminum is ultrafiltrable. Moreover, the Al-detoxification mechanism occurring by treating dialysis patients with the drug Desferrioxamine before dialysis was clarified with such offline techniques. Also, the nature of Al and Si binding proteins in serum has been established using 'offline' liquid chromatography (LC) followed by ETAAS. Most of Al present in serum is bound to transferrin, while Si is weakly bound to several serum proteins (Figure 4).

### Speciation by 'Online' Couplings

Nonchromatographic and chromatographic separation methods coupled 'online' with the atomic detector used exhibit great advantages compared with 'offline' systems, including less sample manipulation,

**Figure 3** Possibilities of hyphenation of different separation techniques to different types of atomic detectors for speciation analysis. FAAS=Flame atomic absorption spectrometry; QC=quartz tube concentrator.

**Figure 4** Aluminum speciation by LC-ETAAS in diluted (1 + 4) human serum. (Reprinted from Soldado Cabezuelo AB, Montes Bayon M, Blanco Gonzalez E, *et al.* (1998) Speciation of basal aluminium in human serum by fast protein liquid chromatography with inductively coupled plasma mass spectrometric detection. *Analyst* 123: 865–869.)

less contamination risk, easy automation, and, in general, more precise and reliable results.

**Nonchromatographic separation coupled to atomic detectors** Flow injection analysis (FIA) strategies may provide an efficient, continuous, and automatic method for preconcentration and/or separation of the sought species from a complex matrix, prior to its final determination. Furthermore, FIA systems can be interfaced easily with atomic detectors making them very convenient in speciation analysis. A typical application is selective preconcentration on

minicolumns of the desired species (e.g., of As(III),  $\text{Pb}^{2+}$ ,  $\text{Hg}^{2+}$ ,  $\text{Cd}^{2+}$ ) in seawater. Species contained in a few milliliters of the sample are injected in the minicolumn allowing for straightforward preconcentration factors of 50–100. Several separation techniques, including dialysis, ion-exchange, and liquid–liquid extraction, can be used for speciation applications in nonchromatographic arrangements coupled to the atomic detector via FIA strategies.

In this vein, many applications have appeared in the literature on speciation of oxidation states, such as Cr(III)/Cr(VI), Fe(II)/Fe(III), As(III)/As(V), Se(IV)/Se(VI). Also, FIA techniques have been used to preconcentrate Sn, Hg, and Pb organometallics mainly from natural waters, sediment, and soil extracts. In particular, great interest has been focused into the speciation of chromium oxidation states in water samples at very low level (nanograms per liter). A FI system with a minicolumn of acidic preconcentration and inductively coupled plasma optical emission spectrometry (ICP-OES) for final detection was developed for a rapid speciation of Cr(VI) and Cr(III) in waters. On sample injection, Cr(VI) is retained in the alumina column whilst Cr(III) is not passing directly to the atomic detector. Afterwards, the retained Cr(VI) is eluted by injection of ammonium hydroxide, as shown in Figure 5, and its analytical signal of emission in the ICP-OES is registered.

An alternative nonchromatographic separation such as continuous liquid–liquid extraction can also provide a simple and effective speciation approach.

After the liquid separation, hydride generation can be used 'online' to increase the sensitivity of the final detection of the volatile species formed in a continuous manner (e.g., speciation of  $\text{Hg}^{2+}$  and  $\text{MeHg}$ , of  $\text{As(III)/As(V)}$  or  $\text{Sb(III)/Sb(V)}$ ).

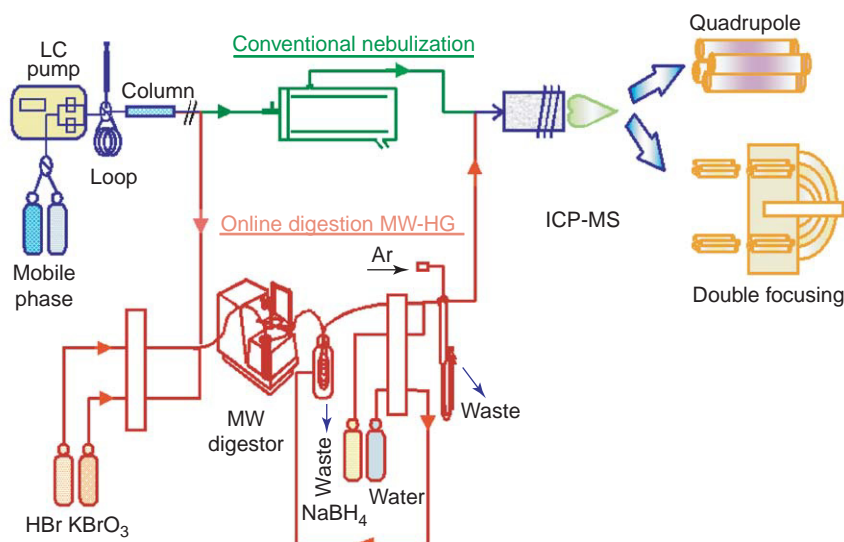

**Chromatographic separation coupled to atomic detectors** Chromatographic separation techniques, both gas chromatography (GC) and LC, have been

coupled to element-specific detectors to form the most powerful and versatile tool for speciation analysis (see **Figure 3**). Flames, heated quartz tubes (QC), microwave plasmas (MIPs), ICP-OES, and ICP-MS have been applied as specific detectors linked to LC or GC. MIP is the source of choice for GC, because of their high excitation efficiency for nonmetallic elements such as S and C, whereas ICP-OES and ICP-mass spectrometry (MS) are the recommended detectors for speciation using LC, because of their multielement capabilities and great sensitivity analyzing liquid samples (in the range of micrograms per milliliter and nanogram per milliliter, respectively, for most of the elements). Moreover, the liquid flow of LC, as well as the gas flow exiting the column in GC, can be directly coupled to an ICP. Also, hydride generation (HG) online atomic detectors can be extremely useful to increase the sensitivity of the final detection in LC-ICP-MS studies. A typical LC-(HG)-ICP-MS coupling proposed for sensitive selenium speciation in urine is given in **Figure 6**.

Whereas the choice of the detection technique is mainly determined by the analyte level in the sample, the selection of the more adequate separation technique is determined by the particular physicochemical properties of the analyte. As shown in **Scheme 1**, for thermally stable and volatile analytes (or able to produce them by easy derivatization) GC is the preferred separation technique. HG or reaction with sodium tetraethylborate is one of the most suitable derivatization procedures. GC has been used

Scheme 1

extensively for identification and determination in environmental samples of different molecular forms of the organometals of Pb, such as tetraalkyllead, dialkyllead ( $R = Et$  or  $Me$ ), used as antiknock compounds in gasoline. Similarly, organotin derivatives (tetraalkyltin, trialkyltin, dialkyltin, and monoalkyltin), widely used as antifouling paints or polymer stabilizers, have been analyzed throughout GC-atomic detectors. As stated before, hydride generation and reaction with sodium tetraethylborate are the most suitable derivatization procedures used for converting the metals and organometals of Pb, Sn, and Hg into volatile compounds for eventual GC separation. Speciation of inorganic- and methyl-mercury in environmental samples has also been carried out using such derivatizations ( $NaBH_4$  forms a 'cold vapor' of mercury with  $Hg^{2+}$  and a hydride with  $CH_3Hg^+$ ).

For nonvolatile, thermolabile, or charged metal-containing compounds LC is preferred. LC is more versatile than GC owing to the diversity of possible separation mechanisms in an LC column: reverse-phase, ion-exchange, size-exclusion chromatography (SEC) are the most used. Ion-pair formation, chiral and affinity chromatography have also been employed. The choice of a particular separation mechanism depends on the analytical problem to be solved: for instance reverse-phase chromatography is recommended for separation of hydrophobic biomolecules and their complexes (e.g., cobalamins, organoarsenic, and organoselenium compounds). Ion exchange is an ideal technique for separation of small charged organometallic ions (e.g., organoarsenic, organoselenium species, etc.) and also for charged

**Figure 7** Multi-element speciation of MTs by FPLC coupled online to ICP-MS and UV-visible spectrometry. (Reprinted from Ferrarello CN, Fernandez de la Campa MR, Carrasco JF, and Sanz-Medel A (2000) Speciation of metallothionein-like proteins from the mussel *Mytilus edulis* at basal levels by chromatographic separations coupled to quadrupole and double focussing magnetic sector. ICP-MS. *Analytical Chemistry* 72: 5874–5880.)

species of biomolecules (e.g., Cd-metallothioneins). Of course, size exclusion should be used for a fractionation in terms of the molecular size of the metal-bioligands (e.g., proteins, polypeptides, etc.). So far other mechanisms such as ion-pair formation, chiral recognition, or affinity chromatography are rather scarce in the speciation analysis literature.

In recent years, many analytical strategies for elemental speciation analysis, particularly in (bio)medical speciation, make use of LC-atomic detector hybrid techniques. Most frequently studied elements include As, Pb, Cd, Sn, Hg, Se, Cr, and Al both in biological and environmental samples. The capability for multi-elemental detection of ICP-MS can be most useful in such analysis. An illustrative example of multi-element trace-element speciation is metallothionein proteins (MT) from rabbit liver by LC-ICP-MS. Comparative profiles for Cd, Zn, Cu, and S obtained for MTs from rabbit liver, using a fast protein liquid chromatography (FPLC) column coupled to ICP-MS are shown in Figure 7, using molecular and specific detectors.

Capillary electrophoresis (CE) offers several advantages as compared to LC for bioligands separation including: low sample volume requirements, high efficiency, ability to separate positive, neutral (with special buffers), and negatively charged species in one single run and at comparatively high speed. In principle, a combination of the advantages of CE for the convenient separation with the high sensitivity and selectivity of ICP-MS detection would provide a powerful technique for elemental speciation. Even if the sensitivity of such CE-ICP-MS systems is poor, this coupling has now been applied to the analysis of a wide variety of compounds, including small metal ions, amino acids, protein digests, protein mixtures, and large neutral or electrically charged biomolecules.

In any case, speciation analyses by LC-ICP-MS and GC-ICP-MS (if possible) seem to provide so far the more straightforward, reliable, and sensitive approach for real-life speciation analysis in complex environmental, biological, or clinical samples.

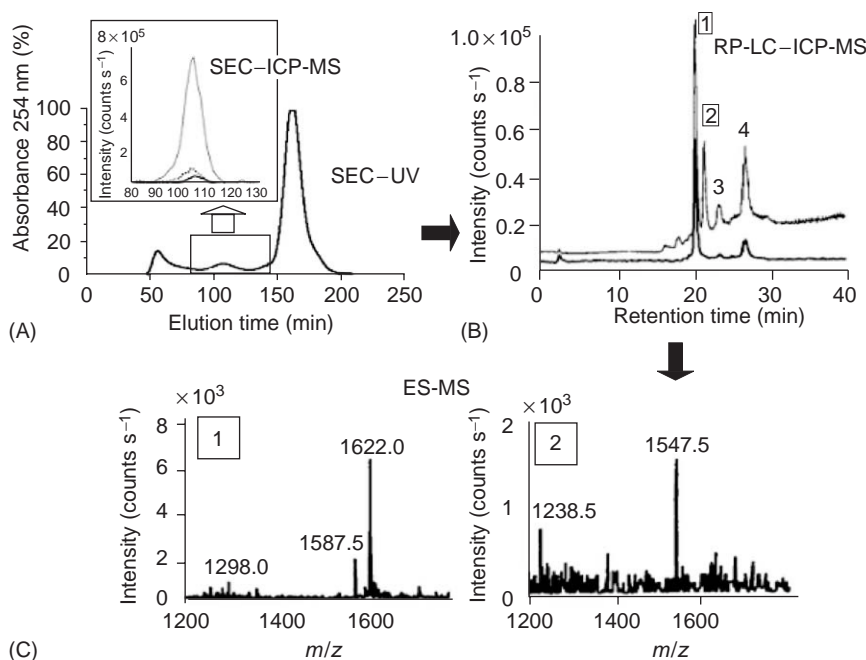

## Likely Developments

There is a worldwide recognition that the chemical, toxicological, biological, and clinical properties of a given element are critically dependent on the actual

chemical form in which the element occurs. The need for 'speciated' information has prompted the development of different analytical strategies and techniques to provide such information. Among them, the combination of a chromatographic separation with a sensitive and element-specific detector has become the more popular and powerful tool for real-life speciation analysis. The initial use of such hybrid techniques to obtain speciated information in environmental issues (i.e., speciation of anthropogenic organometallics of Pb, Hg, or Sn) has been extended now to the difficult speciation of trace elements in biological material of the most varied living organisms.

Speciation analysis has been one of the major developing areas of analytical chemistry during the last 15 years and a great number of new developments are expected in this analytical field in the near future. In particular, some areas where important developments can be envisaged include:

- Development of simpler analytical methodology and commercial instrumentation. Elemental speciation analysis is not yet routine, due to lengthy and cumbersome analytical protocols. Moreover, many methods have been developed for expensive MS detectors, only available in a limited number of laboratories. Simple and low-cost

**Figure 8** New trends in speciation: Separation of Cd-metalllothionein isoforms by: (A) SEC with UV and ICP-MS detection, (B) reversed-phase-LC-ICP-MS of the main Cd containing species eluted by SEC, (C) ES-MS of the peaks labeled as 1 and 2 in the RP-LC-ICP-MS chromatogram. (Reproduced from Polec K, García-Arribas O, Pérez-Calvo M, *et al.* (2000) Identification of cadmium-bioinduced ligands in rat liver using parallel HPLC-ICP-MS and HPLC-electrospray MS. *Journal of Analytical Atomic Spectrometry* 15: 1363–1368.)

instrumentation and reliable methods are needed to achieve routine speciation analysis. Future developments in this area are expected, but they are closely related with the introduction of commercial instrumentation for analytical speciation by instrument manufacturers.

- Developments of quality assurance of the analytical speciation procedures and results are of prime importance at this point. Validation of new methodologies should be carried out if possible with certified reference materials (CRMs) (with a matrix as similar as possible to the real sample certified for the sought species). Unfortunately, very few CRMs are commercially available today for chemical speciation. Thus, alternative approaches for validation using complementary methods based on different mechanisms of separation and complementary detectors are now in order.
- Improvements in the sample pretreatment procedures. Sample cleanup, preconcentration, and preservation procedures of natural species are urgently needed. There is no guarantee that transformation of elemental speciation along the whole analytical procedure does not take place. In this sense, the use of isotopically labeled compounds using an adequate separation technique coupled to ICP-MS is being established. It seems clear that the use of isotopically enriched species, synthesized for the purpose, will become an important tool for validation of speciation results.
- Identification/confirmation of the species. A natural extension of the present popular use of ICP-MS to investigate metal-containing biomolecules (e.g., to 'screen' new metal-biocompounds) is to identify and confirm the whole chemical nature of the new species. To do so, molecular-specific detection techniques such as matrix-assisted laser desorption/ionization time-of-flight or electrospray-tandem mass spectrometry, following a powerful electrophoretic or chromatographic separation, are required. Figure 8 illustrates with a typical example the new trends in speciation analysis to identify/confirm the bioligands associated to the element of interest.

The concept of chemical speciation and speciation analysis is continuously evolving in such a way that the discovery and molecular elucidation of new (semi) metal-biomolecules are now possible via speciation analysis with hyphenated techniques. Of course, a discovered metal-biomolecule can be the signature of a new biochemical reaction mechanism paving

the way to deeper understanding of biochemical pathways of the element. Thus, the fate of trace and ultratrace elements in living organisms and their role in health and disease (even at such minute amounts) could be more properly understood via speciation information.

### Introduction

Speciation analysis in waters, sediments, and soils is the measurement of the different chemical forms of trace constituents such as metals, organometals, and inorganic ions. Interest in speciation analysis is driven by the fact that analyses of total element concentrations fail to reflect the separate chemical, physical, and biological properties that individual species might possess. Assessing the toxicity and bioavailability of trace elements is a major focus of speciation analysis as transport across the cell membranes of living organisms (bioavailability) and potential toxicity vary greatly with chemical form. Historically, the greatest focus of speciation analyses has been on metals (and metalloids).

Speciation analysis can involve the measurement of discrete chemical compounds (e.g., methylmercury chloride, tributyltin oxide, arsenobetaine), or in some cases different oxidation states; or the identification of common classes of compounds that might be operationally defined on the basis of their reactivity, size, or some other physicochemical property. Speciation analysis methods are generally more complex than procedures used for measuring total metal concentrations. This review focuses primarily on trace elements; the diverse speciation of carbon (i.e., organic chemistry) and the analysis of organic compounds are not covered.

In natural waters, trace elements can be present in a variety of species (**Figure 1**). Colloidal particles containing mixtures of hydrous iron and manganese

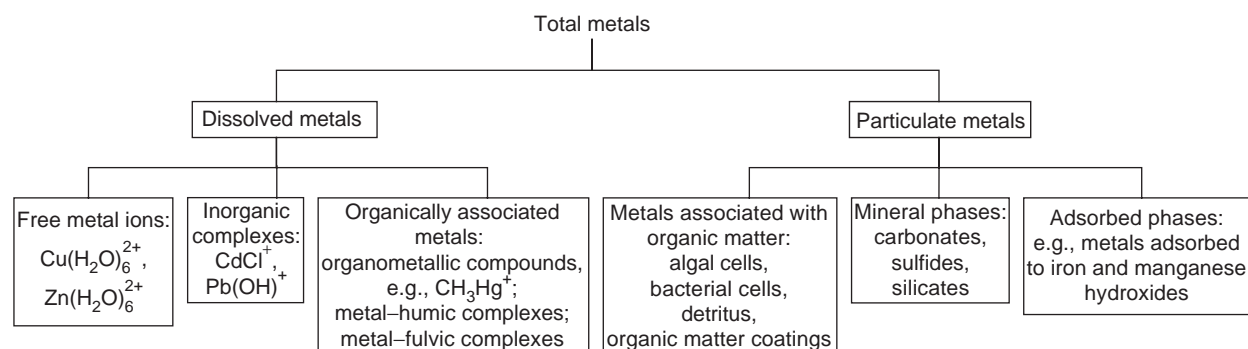

oxides, and organic macromolecules represent an important compartment for many trace elements. Generally a poor correlation exists between total trace metal concentrations and biological effects, and for several metals, bioavailability is better correlated with the concentration of simple aquated ion and inorganic complexes.

In aquatic sediments or soils, there are also a range of trace elements species ranging from ions exchanged to particles, to those bound to organic matter or in various inorganic forms (e.g., oxides, carbonates, sulfides) or as more inert crystalline mineral phases. As in waters, speciation studies in soils and sediments are generally undertaken to better understand the bioavailability of toxic substances and to investigate transport pathways to and from other parts of the ecosystem. Sediment and soil pore waters (soil solutions) are of particular interest because they are in equilibrium with the solid phase and are the medium for contaminant uptake by plants and many other biota. The techniques used for speciation analysis in these aqueous samples differ little from those for waters.

### Analytical Methods

#### Sample Collection and Storage

Trace elements may be present in natural samples at concentrations of parts per billion and lower. The challenge with speciation analysis is frequently the contamination-free sampling of these matrices in a manner that does not perturb solution chemistry and speciation. The stability of samples during storage is a critical issue confronting speciation analysis. Biota and solid samples are generally preserved frozen. For waters, refrigeration at 4°C and storage in the dark is generally thought to be the best storage procedure as

**Figure 1** Types of metal species in natural waters.

it slows chemical reactions and biological processes. Freezing is not generally recommended as it can rupture cells and cause precipitation of some constituents. An alternative approach is the selective preconcentration of certain metal species by immobilization onto selective adsorbents in the field. This is particularly appropriate for the analysis of redox-sensitive species. Given the uncertainties in this area, it is highly recommended that validation tests be carried out to characterize the effects of storage on sample stability.

Concerns over the validity of sample storage have stimulated interest in the development of *in situ* methods for trace element speciation. This includes microelectrodes and various sensors. Examples of this measurement approach are given below.

### Separations Based on Size

One of the easiest separations is that based on size. For waters, these largely divide into the use of filtration or diffusion-based separations.

**Filtration** Traditionally, aquatic chemists have operationally defined 'dissolved' species by filtration through a 0.45 µm pore size membrane. The term 'dissolved' is erroneously used to describe the filterable metal fraction. Filterable and nonfilterable metals are more accurate and appropriate terms. For water samples, filtration through small pore size (0.01–0.45 µm) membranes can be used to separate small particulate and even colloidal species. Ultrafiltration that involves the use of small pore size filters and pressurized filtration has been used to separate macromolecules. Ultrafilters are available with molecular weight cutoffs (MWCO) typically between 1000 and 50 000. Cross-flow ultrafiltration, where water flow is parallel to the surface of the membrane is used for the efficient isolation of colloidal material from large volume samples. Adsorption losses to the large surface area membranes can be an issue and several methods employ correction factors to account for such effects.

**Dialysis** Dialysis membranes can be used to separate species on the basis of their differing rates of diffusion across semipermeable membranes. The size discrimination of commonly used dialysis membranes ranges from typically 14 000 to 1000 MWCO. Dialysis involves equilibration of a large volume of sample (donor) with a small receiving water sample (receptor) contained by a semipermeable membrane. A net diffusive flux occurs until concentrations of the dialyzable species are the same on either side of the membrane, irrespective of any adsorption losses. Equilibrium dialysis where the

sample volume is large and the receptor solution volume is small (e.g., 20–50 ml) is preferred for metal speciation studies as it causes minimal disturbance of bulk solution equilibria. The technique has been applied both in the laboratory and *in situ* in the field, but is not in widespread usage.

**Donnan dialysis** In Donnan dialysis, a cation-exchange membrane separates the donor and receptor solutions. Cationic metal species are transported across the membrane driven by the negative electrostatic potential (the Donnan potential) across the membrane, until equilibrium is achieved. Matching of the ionic strengths of donor and acceptor solutions is necessary. Since cationic species exchange readily compared to neutral and anionic species, it is claimed that the measurement more closely relates to the free metal ion.

The technique has recently found application in studies of metal speciation in soil solutions and pore waters. A Teflon or Kel-F cell is employed with a 30–50 ml donor solution separated from a 200 µl acceptor solution by a strong acid cation-exchange membrane (e.g., Nafion-117). Unless metal concentrations are high, the necessary detection limits may be difficult to achieve.

**Diffusive gradients in thin films** In addition to size and charge, diffusion-limited separation of species can be achieved using a polymer membrane of adequate thickness and pore size overlying a membrane impregnated with a chelating resin. Diffusive gradients in thin films (DGT) is gaining popular acceptance for speciation studies in both laboratory and field, for waters, aquatic sediments, and wetted soils.

A typical DGT device for use in waters consists of a gel impregnated with a chelating resin, covered by a diffusive hydrogel (0.4–0.8 mm thick polyacrylamide) topped with a 100 µm thick, 0.45 µm pore size cellulose nitrate or polysulfone membrane, and contained in a plastic holder with a 2 cm diameter window (Figure 2). For sediment and soil monitoring another sampler that allows sectioning of fine vertical strips is used. Typically, DGT samplers might be deployed for 24–72 h, at the end of which the Chelex gel is removed and placed in a known volume of dilute nitric acid. The elutriate is subsequently analyzed for trace metals by a sensitive technique such as inductively coupled plasma mass spectrometry (ICP-MS).

In waters, the flux of metal ions through the diffusive gel (= accumulated mass  $M$ /(area of membrane  $A \times$  exposure time  $t$ )) will be related to the bulk solution concentration  $C$ , by the relationship:

$$M/At = DC/\Delta g$$

**Figure 2** Schematic diagram of a DGT sampler designed for water quality monitoring and schematic representation of the free concentration profile of ionic species in the sampler when in contact with an aqueous solution. DBL is the diffusive boundary layer. (Reprinted with permission from Zhang H and Davison W (1995) Performance characteristics of diffusion gradients in thin films of the *in situ* measurement of trace metals in aqueous solution. *Analytical Chemistry* 67: 3391–3400; © American Chemical Society.)

where  $D$  is the diffusion coefficient in the gel and  $\Delta g$  the gel thickness.

The diffusive boundary layer in solution also controls the flux of metals and must be kept as small as possible by stirring the solution, or relying on natural mixing in the field. DGT samplers can be deployed in the field or in more controlled conditions in the laboratory. In sediments, the interpretation of metal flux data is more complex as it has to take into account resupply of metals to pore waters by desorption from sediment particles.

DGT methods measure a labile metal fraction, which is a subset of the total dissolved metals concentration. The proportion of the dissolved metal fraction determined will depend on the rate and extent of metal complex dissociation in the presence of

the chelating resin and the diffusion coefficients of the individual metal species. The species that can be measured by the gel are determined by the diffusion layer thickness and the pore size of the gel. Labile metal complexes that can dissociate within the time taken to diffuse through the gel ( $<1$  min) will be measured, together with any inert metal complexes that bind directly to the chelating resin. By changing the composition of the gel and its pore size, it is possible to retard the diffusion of large molecular weight species. This increases the discriminatory capabilities of DGT.

**Permeation liquid membranes** The permeation liquid membrane technique is one of the newest approaches to metal speciation in waters. It attempts to mimic the transport of metal species across a biological membrane, typically using a supported liquid membrane consisting of an organic solvent containing an organic carrier molecule that is selective for the metal of interest and held in the pores of a hydrophobic chemically inert membrane. The membrane is placed between the sample solution and a receiving or stripping solution. One version of this procedure involves the use of a microporous polypropylene membrane (PLM) impregnated with an equimolar mixture of dodecyl-1, 10-diaza crown ether and lauric acid dissolved in a toluene/phenylhexane mixture.

Cyclohexaneethylenediaminetetraacetic acid is used in the stripping solution. Depending on the flow rate and accumulation time used, the flux of metal species across the membrane yields information on the free metal ion and/or labile metal species concentrations in the original solution. PLM has been used in a number of configurations that are rapidly evolving from the original large cell concept (Figure 3) to hollow fiber devices and miniaturized versions. Experiments with model ligands show good agreement with calculated free metal ion concentrations. Measurements using a hollow fiber PLM with a 120 min *in situ* preconcentration have measured picomolar free copper and lead ion concentrations in a range of natural waters.

### Differentiation of Oxidation States

Some elements exist naturally in more than one oxidation state. This applies particularly to metals such as chromium (Cr(III) and Cr(VI)), manganese (Mn(II), Mn(IV), and Mn(VII)), iron (Fe(II) and Fe(III)), antimony (Sb(III) and Sb(V)), thallium (Tl(I) and Tl(III)), arsenic (As(III) and As(V)), selenium (Se(IV) and Se(VI)). The elemental form of many elements can coexist with the ionic forms, but in only a

**Figure 3** Schematic diagram illustrating the operation of a permeation liquid membrane device. (Reprinted with permission from Tomaszewski L, Buffle J, and Galceran J (2003) Theoretical and analytical characterization of a flow-through permeation liquid membrane with controlled flux for metal speciation measurements. *Analytical Chemistry* 75: 893–900; © American Chemical Society.)

few cases is this considered important (e.g.,  $\text{Hg}_0$ ,  $\text{Se}_0$ ). The determination of oxidation states is important for elements such as As, Se, and Cr, because toxicity and reactivity can vary with oxidation state (e.g.,  $\text{As(III)} > \text{As(V)}$ ;  $\text{Cr(VI)}$  is more toxic than  $\text{Cr(III)}$ ). This may be achieved by selective coprecipitation, complexation with oxidation-state specific ligands, electrochemical analysis, or species-selective derivatization and separation by volatilization or liquid–liquid extraction. For example, controlling reaction pH it is possible to selectively evolve hydrides from  $\text{As(III)}$  and  $\text{Se(IV)}$  in the presence of higher oxidation state species. Solid phase adsorbents (e.g., chemically modified silicas) have been used for the selective preconcentration of specific oxidation states.

### Ion-Exchange and Chelating Resin Separations

Equilibration of solutions with various resins has been used to define labile and nonlabile metals species. Contact time is an important factor controlling the split between labile and nonlabile metal species. Batch equilibration, where a fixed mass of resin is added to a sample and then removed after a specified contact time, is suited for timescales of minutes to days whereas passage of samples through resin-filled columns allows much shorter contact times of typically seconds.

Alone, chelating resins such as Chelex-100 in columns have been used to separate weak metal complexes, but have not been widely applied in speciation studies. More recently success has been obtained with the use of tuned Chelex columns, where the column volume is minimized and solution flow rate is maximized, while still giving quantitative recovery of ionic metals. Lability is influenced by

contact time and the nature of the counter ion. Strong cation ion-exchange resins have been used in aluminum speciation studies to separate labile (monomeric) from nonlabile species.

A number of equilibrium ion-exchange methods have been developed to measure free metal ion concentrations in waters. This approach involves the equilibrations of a small volume of resin with a sample. Following the attainment of equilibrium, the amount of metal adsorbed is measured. Calibration is achieved by using matrix-matched solutions of known free metal ion concentration.

### Hyphenated Techniques Involving Chromatographic Separation

A range of chromatographic techniques coupled to element specific detectors has been used in speciation studies to separate individual organometallic species (e.g., butyltins, arsenic species) and to separate metals bound to various biomolecules. The combination of a chromatographic separation with varying instrumental detection systems are commonly called coupled, hybrid, or hyphenated techniques (e.g., liquid chromatography inductively coupled plasma–mass spectrometry (LC–ICP–MS), gas chromatography–atomic absorption spectroscopy (GC–AAS)). The detection systems used in coupled techniques include MS, ICP–MS, atomic fluorescence spectrometry (AFS), AAS, ICP–atomic emission spectrometry (ICP–AES), and atomic emission detection (AED).

Various types of LC have been employed including reversed-phase liquid chromatography (RP–LC), ion chromatography, gel permeation, and affinity chromatography. An important consideration is the compatibility of the eluant with the detection system. Usually aqueous media or low concentrations of miscible organic solvents (e.g., methanol) are used. Using LC, different organometallic species of the same metal are amenable to reversed-phase separations using nonaqueous solvent mixtures and hydrophobic columns (e.g.,  $\text{C}_{18}$ ). Examples include organolead or organotin species analysis. The separation of ionic species, e.g.,  $\text{As(III)}$ ,  $\text{As(V)}$ , monomethylarsonic acid, and dimethylarsinic acid, is best achieved using anion-exchange columns. The separation of various arsenic compounds including arsenobetaine is shown in **Figure 4**. Ion-exchange separations have also been successfully applied to the separation of selenium, chromium, and mercury species in waters.

A major problem with coupled LC procedures is achieving the necessary detection limits for these species, especially in waters. Either some form of preconcentrations is required or the detection system

**Figure 4** Separation of arsenic species by LC-ICP-MS. The chromatogram shows the separation of As(V) dimethylarsenic acid (DMA), arsenobetaine (AB), trimethylarsine oxide (TMAO), arsenocholine (AC), and tetramethylarsonium ion (tetra) on a HHPN Nucleosil 5SA cation-exchange column (mobile phase  $30 \text{ mmol l}^{-1}$  pyridine, pH 3.0, injection volume  $20 \mu\text{l}$ , flow rate  $1 \text{ ml min}^{-1}$ ,  $25^\circ\text{C}$ ). The concentration of each species was  $2 \mu\text{g As per liter}$ . (From Falk K and Emons H (2000) Speciation of arsenic compounds by ion-exchange HPLC-ICP-MS with different nebulizers. *Journal of Analytical Atomic Spectrometry* 15: 643–649; reproduced by permission of The Royal Society of Chemistry.)

needs high sensitivity. The most sensitive detection system for metals is ICP-MS.

Capillary electrophoresis has also been used for separation of organometallic species, although detection limits are poor owing to the very small sample volumes used in this technique. Polyacrylamide gel electrophoresis has been coupled to hydride generation (HG)-AFS to separate selenium in various protein fractions.

GC is widely used to separate volatile organometallic species. The favored approach involves derivatization (e.g., ethylation or hydride formation), preconcentration, chromatographic separation followed by element-specific detection using AAS, AES, or AFS. For species such as methylmercury and methylarsenic compounds, derivatization is normally necessary prior to GC in order to form volatile species. The most common approach has been to convert both inorganic and organometal species via hydridization with sodium borohydride, or alkylation, e.g., using sodium tetraethylborate, to form volatile hydrides or alkylated species, respectively. Not all species of an element are amenable to derivatization. For example, the application of hydridization

**Figure 5** Analysis of butyltin species in coastal waters. Typical chromatogram of an MBT, DBT, and TBT (each  $75 \text{ ng Sn}$ ), analyzed by GC-AAS following aqueous phase ethylation with sodium tetraethylborate. Retention times: A, tetraethyltin 1.7 min; B, triethylmonobutyltin 3.4 min; C, diethyldibutyltin 4.7 min; D, ethyltributyltin 6.6 min. (Reprinted from Bowles KC, Apte SC, and Hales LT (2003) Determination of butyltin species in natural waters using aqueous phase ethylation and off-line room temperature trapping. *Analytica Chimica Acta* 477: 103–111; © with permission from Elsevier.)

to arsenic in a fish tissue extract would not convert arsenobetaine to a hydride. Preconcentration of volatile species, either on solid adsorbents at room temperature or colder (cryogenic trapping using liquid nitrogen). Volatile forms, once thermally desorbed, are also more amenable to sensitive spectrometric detection systems, including atomic absorption, atomic emission, or atomic fluorescence. For these systems, atomization of the separated species is first required, and this has been achieved by a variety of furnace systems, most commonly a quartz tube furnace, but ceramic, tantalum, graphite, plasma, and other variants have also been used. The coupling of effective derivatization, preconcentration, and sensitive detection has led to measurements of subnanogram per liter concentrations of species such as tributyltin (Figure 5) and methylmercury in natural waters.

## Electrochemical Techniques

**Voltammetric techniques** Voltammetric techniques have been widely applied to determine metal contaminants in aqueous media. They involve reduction (or oxidation) at a working electrode with the current associated with the reduction being measured as a function of the electrode potential. Techniques such as differential pulse polarography at a dropping mercury electrode or voltammetry at a hanging mercury drop electrode (HMDE) have detection limits near  $10^{-8} \text{ mol l}^{-1}$ . Greater sensitivity can be achieved using stripping voltammetric methods such as anodic stripping voltammetry (ASV) and cathodic stripping voltammetry (CSV).

In ASV, stripping (oxidation) of the reduced metal is achieved by the application of an anodic potential scan. This technique is applicable to metals that are reversibly reduced at mercury electrodes, including Cu, Pb, Cd, Zn, Bi, Sb, In, and Tl. Detection limits will be dependent on the deposition (accumulation) time, the nature of the stripping waveform (usually either direct current, differential pulse, or square wave), and the electrode type. HMDEs are widely used, although greater sensitivity may be obtained using a mercury film deposited on a glassy carbon substrate. Under optimum conditions, detection limits of  $10^{-11} \text{ mol l}^{-1}$  are achievable. Carbon fiber or iridium wire microelectrodes have also been successfully used as mercury film substrates. They are ideal for small volumes and for high resistance (low ionic strength) solutions.

CSV involves the addition of a ligand of known thermodynamic properties to the solution, equilibration and the accumulation of an adsorbed metal complex on a mercury electrode and its reduction by a cathodic potential scan. CSV measures only the metal species that will react with the ligand, either at the electrode or in solution. The method has found application in ligand competition methods for speciation analysis as discussed below.

Both ASV and CSV measure labile metal concentrations (assumed to approximate the concentration of inorganic metal species and weakly bound organic complexes) and have been used to elucidate the extent of complexation by dissolved organic matter for a range of metals. The value of voltammetric techniques in metal speciation studies lies in the fact that discrimination can be achieved on the basis of their reactivity at the electrode. This will include not only the free metal ion, but those in complexed forms (ML), provided the dissociation of the complex in the diffusion layer is very fast compared to diffusion, i.e., the thermodynamic equilibrium of the dissociation of ML is maintained despite consumption of M at the

electrode surface. Complexes that meet this criterion are termed labile, those that do not are termed inert.

**Ion selective electrodes** Measurement of the free metal ion is an important goal of metal speciation studies in natural waters, because of the tenet of the free ion activity model, that bioavailability is proportional to the free metal ion concentration. Ion selective electrodes respond to the free metal ion activity. A range of ion selective electrodes are available, but only the copper electrode has sufficient sensitivity for use in measurement at realistic environmental concentrations in natural waters. The correct use of the copper ion selective electrode remains a matter of debate, especially its calibration at the very low free metal ion concentrations using metal ion buffers and the applicability of this procedure to natural samples.

## Ligand Competition Techniques

There have been a number of approaches to the use of ligand competition (or exchange) reactions for speciation analysis in solution.

Equilibrium ligand competition has been most widely used in combination with stripping voltammetric techniques to determine the free metal ion concentrations and the relative importance of other metal binding ligands in natural waters. For example, for copper, ligand competition with catechol was measured by differential pulse cathodic stripping voltammetry (DPCSV). For cadmium, ethylene diamine was used as the ligand with differential pulse ASV detection, and for nickel, dimethylglyoxime with DPCSV. The methods involve the addition of a known amount complexing ligand, and titrating the sample with added ionic metal, allowing appropriate equilibration before DPCSV measurements. The titration data allow calculation of the free metal ion concentration in the sample and the concentrations and binding constants of the other major ligands in the sample, usually simplified to a one- or two-ligand complexation models. This approach has found greatest application in elucidating metal speciation in seawater.

The reaction of metal species with added colorimetric ligand has also been utilized to gain speciation information. A classic example is the use of pyrocatechol violet as a spectrophotometric reagent to determine labile monomeric (fast reacting) and organic aluminum species.

## Modeling Speciation in Waters

There are a number of computer codes available for calculating solution equilibria and the speciation of trace metals in natural waters. Programs such as

MINEQL and MINTEQA2 are now widely used by aquatic scientists. Similar models (e.g., GEOCHEM and SOILCHEM) are used by soil scientists. The effective use of such computational models requires critical knowledge of key reactions and judicious selection of the appropriate stability constants. Recent research endeavors in this area have been directed toward describing metal interactions with natural organic matter (NOM). This is an immense challenge owing to the polydisperse, heterogeneous nature of NOM. Biotic ligand models (BLM) have recently been developed which predict acute metal toxicity to some aquatic organisms. BLM models assume that metal toxicity is related to free metal ion binding to a specific ligand at the cell surface of unicellular organisms or at the gill surface in fish. The models take into account proton, calcium, and magnesium ion competition for the binding sites and assume a simple relationship between the bound metal concentration and toxicity.

### Speciation of Inorganic Ions

The speciation of nitrogen and phosphorus are important areas of nutrient chemistry in both waters and soils. Most methods are based on colorimetry with sample pretreatment. For waters, flow injection analysis techniques are usually preferred because of their ability to handle high sample throughput. These species are usually individually determined following standard analytical procedures. Analytical methods are available for the determination of nitrate, nitrite, and ammonia. Only ammonia exerts toxic effects on aquatic biota and then only in the unionized form. Phosphorus in waters exists mainly as orthophosphate, but also as polyphosphates or organophosphorus compounds. It is normal to measure total and reactive phosphorus. Sulfur speciation is also of interest, the species including sulfate, sulfite, thiosulfate, sulfur, hydrogen sulfide, and other sulfides and polysulfides. As for nutrients, sulfur speciation analysis has used a range of routine analytical procedures. Most methods employ ion chromatography or colorimetry.

Cyanide speciation is of particular interest in industrial effluents. Weak acid dissociable cyanide species are determined by distillation following acidification of the sample and measurement of the trapped cyanide in alkaline solution. Individual metal cyanide species may also be determined by LC.

## Speciation Analysis in Solids

### Direct Measurement of Speciation

Some surface speciation information may be obtained using X-ray photoelectron spectroscopy, Auger

spectroscopy, and secondary ion mass spectrometry (SIMS). The use of these high vacuum techniques may cause artifacts owing to sample dehydration. X-ray absorption near edge spectrometry and extended X-ray absorption fine structure are very promising direct measurement techniques, which give information on solid and solution phase speciation with reasonable sensitivity. Using a combination of both techniques, it is possible to deduce oxidation states, the identity of nearest neighbor atoms, and bond distances. Sample preparation is minimal, however, these procedures are restricted in their applications as they require a synchrotron to generate high energy radiation.

### Selective Dissolution Procedures

A number of operational procedures are available to determine potentially mobilizable species in solids. These involve the extraction of samples with acid, alkali, or a complexing agent. With respect to metal bio-availability, a more useful extraction is to use either cold  $1 \text{ mol l}^{-1}$  hydrochloric acid or  $0.5 \text{ mol l}^{-1}$  ethylenediaminetetraacetic acid, on the basis that this will not react with the more intractable phases. The measured values probably exceed that which might be released by at the lowest gut pH of any organisms, but it is at least an improvement on 'total' metal measurements. Various enzyme 'cocktail' mixtures have also been used to mimic metal mobilization in the digestive tracts of organisms.

The most sophisticated approaches involve sequential chemical leaches with extractants that have selectivity for particular mineral phases. For metals, those 'fractions' traditionally measured include:

- ion-exchangeable surface metals (removed with a  $\text{MgCl}_2$ , ammonium acetate, or other salt solution);
- carbonate minerals (removed with dilute acetic acid);
- metals associated with easily reducible iron and manganese oxides (using acidified hydroxylamine hydrochloride);
- metals bound to organics or sulfides (released by hydrogen peroxide); and
- a residual inert, mineralized fraction that requires strong acid digestion (nitric and hydrofluoric acids).

There are many problems with carryover and read-sorption that can make these procedures 'poorly selective', and the value of the speciation information is often questionable, although it has been extremely widely applied.

A recent speciation interest with respect to sediments has been the role of reactive sulfides, notable

FeS, in moderating metal bioavailability. Provided it is present in excess, FeS will exchange with soluble metal ions forming insoluble metal sulfides (e.g., Cu, Pb, Zn, Cd). Acid volatile sulfide (AVS) is measured by reaction with dilute acid under nitrogen. Under these conditions, ordered phases such as pyrite do not react. An excess of soluble (potentially bioavailable) metals will only be seen in the pore waters if the exchange capacity of the FeS for these metals is exceeded, so provided there is an FeS excess there should be no toxicity due to pore water metals. It is common to assess this from the difference between the molar AVS concentration and the sum of the molar concentrations of metals that are released simultaneously in the dilute acid treatment.

For organometallic species, the analytical challenge involves quantitative extraction of the species from the solid phase without appreciable transformation to other forms. Various liquid extractants have been used such as methanolic hydrochloric acid (extraction of organotins). Strong alkali digests (KOH or tetramethylammonium hydroxide) will dissolve most tissue without breakdown or transformation of arsenic species. As an alternative to liquid extraction, methylmercury species may be extracted from solids using steam distillation. Specific reaction conditions will affect the recovery of various species and rigorous validation of extraction procedures is therefore recommended.

## Quality Control in Speciation Analysis

Quality control (QC) is as important in speciation analyses as it is in other areas of analysis. While there are a growing number of certified reference materials available that contain specific forms of an element, for example, tributyltin, methylmercury, this is the exception rather than the rule. Instead, other standard QC approaches need to be used. These include the use of spike-recovery tests and internal standards, comparisons with the results from other methods,

and interlaboratory comparisons. Standard protocols have yet to be documented for many speciation methods, and if these are to be incorporated in regulations as they are now starting to be, considerations of appropriate certified reference materials and QC measures need to be given high priority.

## Introduction

Elemental speciation is the quantitative determination of individual chemical forms of an element.

Considerable interest has developed in speciation since the early 1960s involving the biological and environmental sciences when it was observed that the toxicity and mobility of metals is dependent upon their chemical form. Speciation may also involve the characterization of the bioavailability of an element from complex matrices such as soil or sediments.

This article provides an overview of the major issues involving elemental speciation in environmental

samples. Following a discussion of several example elements, sampling, sample preparation, and calibration procedures are discussed. Instrumentation for speciation is reviewed, including separation techniques and detection methods. The conclusion is a detailed discussion of a particular application of speciation involving environmental samples.

## Speciation of Example Elements

Metal compounds exist in a wide variety of chemical forms that may be classified as inorganic, complexed ions, or organometallic. A variation in the toxicity of different inorganic oxidation states exists for some metals. Perhaps most widely studied element with this characteristic is chromium. Chromium has been introduced into the environment from a variety of industrial processes that include tanning, chrome plating, stainless steel welding, spray painting, dye manufacturing, and cleaning aircraft and automobile parts. Chromium(III) is an essential element at trace concentrations that is characterized by low uptake by biological organisms. However, chromium(VI) is considerably more available and toxic to biological organisms as chromate or dichromate. It has also been classified as a carcinogen by the US Environmental Protection Agency (EPA).

Organometallic compounds may have very different environmental toxicities than inorganic compounds. Alkylated mercury compounds (e.g., methyl mercury) are far more toxic than inorganic mercury (although these species are also regarded as toxic). A number of anthropogenic activities release mercury into the environment, which may then be methylated by microorganisms. Although the concentrations of mercury may be in the low part-per-billion range in the environment (e.g., the ocean) and the methylation process is relatively inefficient (1%), methyl mercury may accumulate to micrograms per gram levels in top predators in the aquatic food chain.

Organotin compounds (e.g., tributyl tin (TBT)) are of considerable interest for environmental speciation because of their past use as pesticides, algicides, fungicides, and molluscicides. TBT was employed as the active ingredient on boat hulls to prevent the accumulation of barnacles and other fouling organisms that increase fuel consumption and maintenance costs. These compounds accumulated to toxic levels in shellfish and fish, with the first evidence appearing in France in the late 1970s and early 1980s. Legislation was passed in France and other nations that had restricted the use of TBT-based paints. This is in sharp contrast to elemental and inorganic tin, which are characterized by low toxicity and very low rates of accumulation into living organisms.

Arsenic is well known because of its widespread use as a poison in criminal activity. Arsenic has also been widely used for agricultural applications, which include herbicides, pesticides, and wood preservatives. These applications have been reduced in recent years due to concerns about its toxicity, and the US EPA has recently reduced the acceptable limit of arsenic in drinking water. Unlike mercury and tin, organometallic forms of arsenic, such as arsenobetaine, arsenocholine, and some arsenosugars, are relatively nontoxic, while inorganic arsenic(III) (arsenite) and arsenic(V) (arsenate) are highly toxic.

Manganese is the 12th most common element and is characterized by a variety of oxidation states, including Mn(VII), Mn(VI), Mn(IV), Mn(III), and Mn(II). It is most commonly found as the mineral, pyrolusite ( $\text{MnO}_2$ ). Manganese is used in a variety of industrial applications (Table 1). Its most significant applications include metallurgical processes, primarily steel manufacturing, the manufacture of dry-cell batteries, and as a coloring agent for the brick industry. Other applications include glass (coloring agent), chemical industry (dye and paint production), and electronics industry (magnets). An organomanganese compound, methylcyclopentadienyl manganese

**Table 1** Industrial applications of manganese

<i>Chemical form</i>	<i>Application</i>	<i>Function</i>
Mn	Steel manufacture	Scavenger of sulfur and oxygen; increase hardness
$\text{MnO}_2$	Dry-cell batteries	Acts as depolarizer to prevent liberation of hydrogen
$\text{MnO}_2$	Brick	Colorant
$\text{MnO}_2$	Glass	Decolorizer
$\text{MnO}_2$	Hydroquinone production	Oxidizing agent
$\text{MnO}_2$	Ceramic ferrites	Magnets
$\text{KMnO}_4$	Synthesis of chemicals (saccharin, benzoic acid)	Oxidizing agent
Methylcyclopentadienylmanganese tricarbonyl	Gasoline, aircraft fuels	Antiknock agent

tricarbonyl (MMT), has been widely used as an anti-knock agent in aircraft fuel and gasoline.

Although manganese is considered a nutritionally essential trace element, it is known that very high levels of inhaled manganese induce a neurological disorder called manganism. This disease has been most commonly associated with miners, who are exposed to manganese via inhalation, although there have been reports of exposure through food and water. Considerable scientific study of manganism has been performed in recent years because of its similarities with Parkinson's disease. A number of studies have considered the environmental and toxicological impacts of the use of the fuel-additive MMT because of its higher toxicity compared to inorganic manganese compounds.

## Sampling, Sample Preparation, and Calibration

As speciation methodology has developed over the past 40 years, it has become clear that quality control issues such as sampling, sample preparation, and calibration are critical to obtain meaningful results regarding environmental samples. Many early studies were flawed by errors in these methodologies that produced inaccurate data. Here some of the major issues in sample handling and treatment are discussed.

### General Considerations of Environmental Sampling

Considerable planning needs to be performed to develop a sampling procedure that is representative of the environmental system of interest. First, it is necessary to collect samples from sites that are representative for the study. One should also make certain to collect appropriate types of materials (e.g., atmosphere, hydrosphere, biosphere, pedosphere, lithosphere) to answer the environmental question of interest. A representative number of specimens for each material need to be sampled and subsequently analyzed. Although ideally this value should be calculated based on the known values of the standard deviation of the samples, in many cases the variance is unknown and it is necessary to select the number of samples based on an estimated value. Lastly, it is necessary to account for weather conditions and natural seasonal variations in the concentrations of metal species in biological samples.

It is essential to maintain information about each of the chemical species of interest during all analytical procedures. This can be achieved by ensuring that no changes occur during sampling, storage, and analysis, or by quantitative derivatization of the

**Table 2** Concentration of example elements in laboratory glass and plasticware

<i>Material</i>	<i>Concentration range (<math>\mu\text{g per g}</math>)</i>	
	100	10–0.1
Glass	Al, K, Mg, Mn, Sr	Fe, Pb, B, Zn, Cu, Rb, Ti, Ga, Cr, Zn
Polyethylene/polypropylene	Na, Zn, Ca, Al, Ti	K, Br, Fe, Pb, Cl, Si, Sr
PTFE	K, Na	Cl, Na, Al, W

analytes into stable compounds. Also, most speciation studies involve trace or ultratrace analysis, so it is critical to avoid contamination and loss of analytes throughout sampling, storage, and analytical procedures. This includes the use of clean sampling tools and collection vials that will not induce contamination for the analytes and by the use of careful cleaning protocols. Examples of elements present in measurable concentrations in laboratory glass and plasticware are listed in **Table 2**. For example, when doing speciation analysis of zinc, zinc-doped stoppers must be avoided. Samples to be analyzed for mercury should be stored in glass.

One approach to investigate contamination of collection tubes is by the analysis of a certified reference material, after storage for a length of time representative of the study, to see if the certified value is obtained. However, there are relatively few elements certified at these low concentration levels. Alternatively, the sample containers may be rinsed with acid or other suitable solutions, followed by determination of the analyte concentration in the leachate. Although easy to perform, this procedure may not accurately represent the amount of contaminants picked up by the samples.

### Collection and Storage of Specific Environmental Samples

Although it is beyond the scope of this article to consider detailed collection and sample preparation procedures for environmental samples, here are some general considerations for speciation analysis of air, water, biological material, and soils/sediments. The collection of samples in air has focused upon the determination of hydrides and methylated compounds of elements such as arsenic, lead, mercury, and tin. The sample may be introduced into a preevacuated container, or with a pump. The analytes may be isolated using cryotrapping techniques or adsorbent cartridges. For best results, it is recommended to collect the entire gas sample in a container, coated

with an inert material such as polytetrafluoroethylene (PTFE), followed by analysis within 24 h.

The specifics of sampling and storage for water are dependent upon the sample. Clearly, different procedures are required for groundwater, seawater, waste water, and atmospheric precipitation. Samples should be collected at a reproducible location and depth below the surface. In general, the contamination control procedures discussed above should be followed. Although it may be necessary to remove bacteria and other suspended solids from samples using membrane filters, it is necessary to investigate these methods for possible contamination or influence upon the types of species present. Acidification of water samples may also induce chemical transformations of some elements.

Biological samples are particularly challenging because of wide variations in the accumulation of metal compounds in different organisms, differences in accumulation in various tissues, and the potential for chemical transformation of compounds during and subsequent to sampling. Sampling strategies need to include an appropriate number of individuals and a well-defined protocol to isolate the biological tissue of interest. It is normally advisable to remove tissue followed by immediate storage in liquid nitrogen to prevent degradation. Although it is normally necessary to remove surface contamination such as soil or sediment from plant samples, washing procedures may remove or transform some chemical compounds.

A major issue in the speciation of soils and sediments is obtaining a representative sample. It is necessary to collect relatively large quantities of samples using tools (e.g., shovels, corers, sediment traps) and collection containers that do not introduce contamination. As with biological samples, one must consider the effects of collection and storage upon the integrity of the chemical species. For example, air-drying of soil samples that were collected under anoxic conditions may be expected to cause significant changes in sample composition.

### Calibration and Standard Reference Materials

Analytical methods may be classified as absolute or relative methods. 'Absolute methods' have the advantage of producing results without comparative measurements, but are generally restricted to pure samples because of their susceptibility to interferences from sample matrices. 'Relative methods' involve the comparison of the signal response of a detection system ( $S$ ) compared to calibration samples of known concentration. Normally linear calibration graphs are employed because of their ease of

preparation from a few standards and their description by the following simple relationship:

$$S = kc + b \quad [1]$$

where  $c$  is the concentration of the analyte;  $k$  the slope, reflecting the sensitivity of the method; and  $b$  is the  $y$ -intercept, which is normally close to zero.

Ideally the analyst would have a wide variety of samples, called certified reference materials (CRMs) or standard reference materials, with well-defined analyte concentrations. Practically, however, it is too expensive to produce the vast number of these materials that would be needed for all elements and samples. Instead, calibration is typically performed using aqueous standards, and the CRMs are employed as samples to verify accuracy.

The creation of CRMs for speciation analysis was a major analytical challenge because of the instability of many chemical species of interest. However, since the 1980s, five organizations have developed CRMs for environmental speciation: the European Commission (BCR, Brussels, Belgium), International Atomic Energy Agency (IAEA, Vienna, Austria), National Institute for Environmental Studies (NIES, Japan), the National Institute for Standards and Technology (NIST, Gaithersburg, MD), and the National Research Council Canada (NRCC, Ottawa). A list of some available CRMs for speciation analysis is presented in Table 3. It should be noted that a relatively limited number of materials are available for speciation analysis that are certified for a handful of environmentally significant chemical species. It is clearly desirable to have CRMs available for more compounds and also with a wider range of chemical species.

**Table 3** Representative certified reference materials for speciation analysis available from European Commission (BCR), International Atomic Energy Agency (IAEA), National Institute for Environmental Studies (NIES), National Institute for Standards and Technology (NIST), and National Research Council Canada (NRCC)

<i>Producers</i>	<i>Sample and certified compounds</i>
NIST	Cr(III) and Cr(IV) in water
NIST, IAEA, NRCC, BCR	Mercury and methyl mercury in fish or shellfish
BCR, IAEA	Mercury and methyl mercury in sediment
NRCC, BCR	Butyl tin compounds in sediment
BCR	Butyl tin compounds in shellfish
NIES	Total tin and tributyl tin compounds in fish tissue
BCR	Organoarsenic compounds in fish tissue
BCR	Trimethyl lead in urban dust

## Instrumentation for Environmental Speciation Analysis

Instrumentation for speciation requires the ability to quantitatively determine various chemical species of an element. The most widely used instrumental configuration includes a system to separate the chemical species, such as chromatography or electrophoresis, and an atomic spectrometry detector, which provides high sensitivity and specificity for the separated compounds of the element of interest. **Figure 1** illustrates instrumentation that was employed for manganese speciation analysis.

### Separation Systems

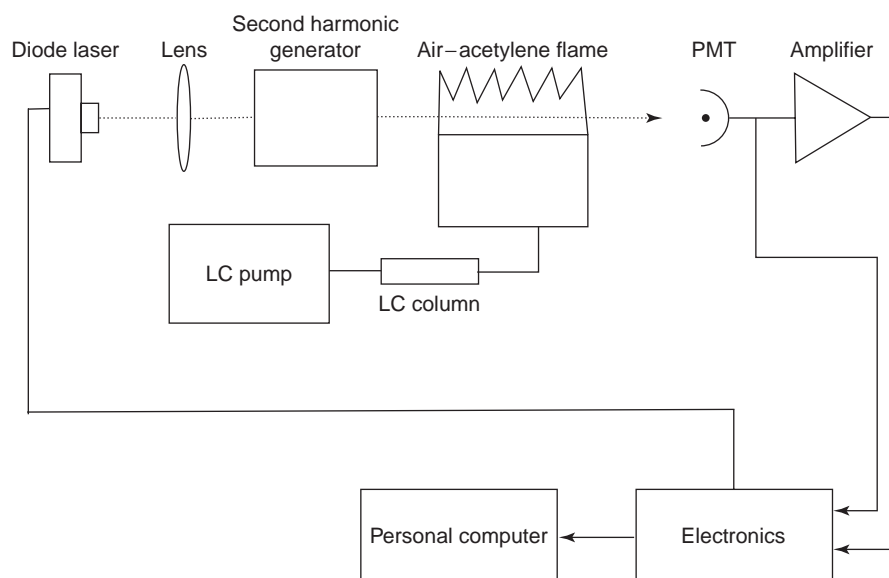

The most commonly used separation techniques for speciation include gas chromatography (GC), liquid chromatography (LC), and capillary electrophoresis (CE). GC has the major advantage that the analytes exiting the separation system are in the gas phase, which allows high sample introduction efficiency (essentially 100%) into the detector, resulting in high sensitivity. Other advantages include the higher chromatographic efficiency of GC compared to liquid chromatography (LC) (narrower peaks) and increased detector stability due to the absence of solvent introduction. Its major limitation is that it is restricted to compounds, which are volatile and thermally stable. A relatively limited number of chemical species can be determined directly by GC. These include tetraalkyl lead, metallic and methyl mercury, and sulfur compounds.

In order to determine nonvolatile elemental species, it is necessary to employ chemical reactions to

produce volatile, relatively nonpolar, thermally stable compounds. These 'derivatization reactions' involve one of the three general classes: production of volatile compounds in aqueous solution, involving hydride generation or ethylation; production of volatiles in organic solution, e.g., butylation using Grignard reactions; or formation of a volatile chelate, such as acetylacetonates or dithiocarbamates. The efficiency of derivatization reactions is highly dependent upon the sample matrix, and hence it is normally necessary to perform recovery studies for each category of sample (e.g., soil, sediment, etc.). Internal standardization or isotope dilution procedures are commonly employed to correct for these effects.

LC has the primary advantage of being applicable to virtually all analytes without derivatization procedures. In addition, a wide variety of stationary phases are available in conjunction with an array of solvent systems to separate analytes. LC techniques routinely used for speciation include reversed phase LC (RP-LC), reversed phase ion pair LC (RPIP-LC), and ion exchange LC (IE-LC). RP-LC, which uses a polar mobile phase with a nonpolar stationary phase (typically silica to which alkyl chains are chemically bonded), is best suited for the separation of nonpolar and slightly polar compounds, such as organometallic species.

RPIP-LC uses the same stationary phases employed in RP-LC, but with the addition of a salt to the mobile phase that contains an ion with a polar head group and a nonpolar tail. These salts are called 'ion pair reagents'. Examples of these compounds include tetraalkylammonium salts and sodium alkyl

**Figure 1** Example of experimental setup of instrumentation employed for manganese speciation.

sulfonates. RPIP-LC is widely used for speciation because it can be used to simultaneously separate ions and uncharged species.

IEC-LC employs a stationary phase that includes ionic functional groups, such as sulfonate or quaternary ammonium, bonded to a supporting material. These functional groups interact electrostatically with analytes having the opposite charge, and hence IEC-LC is employed for the speciation analysis of charged compounds. Aqueous mobile phases are generally employed.

CE is a very powerful tool for chemical separation, providing very high efficiency and the ability to use several separation modes. Moreover, since there is no stationary phase to interact with the analytes, CE has a reduced risk of changing species integrity compared to chromatography techniques. In spite of these potential advantages, CE has not been widely used for speciation, primarily due to the small sample volumes employed, typically a few nanoliters. This results in concentration detection limits 100 times higher than LC methods. The low volume also creates problems in interfacing CE to the detection system. Moreover, artifact peaks have also been reported that may be difficult to distinguish from analyte signals. CE is consequently best suited to environmental samples that include analytes that are difficult to separate by LC and are present at relatively high concentrations.

### Detection Systems

Detection systems for speciation have commonly consisted of atomic spectrometry instrumentation. One of the earliest techniques employed was flame atomic absorption spectrometry (FAAS). Sample is introduced into a flame using a pneumatic nebulizer system. The light source for atomic absorption is a low pressure (a few Torr) hollow cathode lamp (HCL) that includes a ceramic cylinder cathode coated with the pure metal or a compound of the analyte. Application of 150–300 V across the electrodes produces a plasma that results in a narrow atomic emission line that is absorbed by analyte atoms in the flame. FAAS instrumentation is relatively inexpensive and easily interfaced to chromatography systems. However, HCL-FAAS is characterized by relatively poor sensitivity that has limited its use for practical speciation analysis.

An alternative to HCLs for FAAS is the use of semiconductor diode lasers (DLs), which offer higher sensitivity, longer linear calibration graphs, high reliability, small size, and easy operation (**Figure 1**). Diode lasers produce infrared radiation that is converted to visible light using a process called ‘second

harmonic generation’. DL-FAAS is a low cost, high sensitivity detector for speciation.

More recently, the inductively coupled plasma (ICP) has become the detection system of choice for most applications, either as a source for optical emission spectrometry (OES) or mass spectrometry (MS). The ICP is produced by coupling energy from a radio-frequency generator (generally 500–2000 W at 27.12 MHz) into argon gas using a water-cooled copper coil. Subsequent to the seeding of the argon with electrons, collisions between charged species occur that cause ionization of gaseous atoms. One of the major advantages of the ICP for real sample analysis is its relatively high temperature (5000–6000 K in the analytical region), which minimizes chemical reactions between the analyte and the sample matrix. Sample introduction is normally performed using a pneumatic nebulizer system. Modern detection systems for ICP-OES employ charge-coupled devices (CCD) that allow nearly simultaneous determination of 20 or more elements. Although ICP-OES provides superior sensitivity to FAAS for speciation analysis, it too is insufficiently sensitive for some applications.

ICP-MS is the most widely used detection system for environmental speciation, based on its excellent sensitivity, long linear calibration graphs, and ability to determine many elements simultaneously. A fraction of the plasma passes through an interface into a mass spectrometer where the ions are distinguished on the basis of mass-to-charge ratio. Although most ICP-MS work has employed a quadrupole filter for mass analysis, other mass analyzers are commercially available, including time-of-flight, ion traps, and double focusing sector instruments. The high concentration of salts employed for LC may introduce problems for ICP-MS, such as blockage and corrosion of the interface, and increased spectral interferences. However, its advantages make ICP-MS the technique of choice for environmental speciation analysis.

### Example of Application of Environmental Speciation

An example of environmental speciation involves the determination of the manganese containing fuel additive, methylcyclopentadienyl manganese tricarbonyl (MMT), and its derivative, cyclopentadienyl manganese tricarbonyl (CMT). As discussed above, the toxicity of this compound and concerns about human exposure to inhaled manganese have raised concerns about the widespread use of this compound in gasoline. Instrumentation for this work (**Figure 1**) involved the combination of LC coupled with

**Figure 2** Chromatogram of inorganic manganese, CMT, and MMT by LC-DL-FAAS.

**Table 4** Analysis of environmental samples spiked with MMT

Sample	Added concentration ( $\mu\text{g ml}^{-1}$ )	Reported solubility in water ( $\mu\text{g ml}^{-1}$ )	Determined value by HPLC-DL-FAAS, ( $\mu\text{g ml}^{-1}$ )
Tap water	—	10–70	$36 \pm 2$
Gasoline	8.3	—	$8.0 \pm 0.8$
Human urine	4.0	—	$4.2 \pm 0.3$

DL-FAAS. The speciation instrumentation included a reversed phase  $\text{C}_{18}$  column for the determination of MMT, CMT, and inorganic manganese. The mobile phase was 65:35 methanol/aqueous pH 4 buffer ( $0.05 \text{ mol l}^{-1}$  ammonium acetate).

An example of a chromatogram is shown in **Figure 2**, illustrating good separation between the various manganese-containing species. It should be pointed out that this analysis was performed in less than 3 min, providing rapid analysis. The manganese detection limit for LC-DL-FAAS was 2 ng per ml, with a linear dynamic range of 3 orders of magnitude.

The suitability of DL-FAAS to perform practical analysis was evaluated by the addition of MMT to samples of tap water, gasoline, and human urine (**Table 4**). Saturated solutions of MMT were prepared to simulate its determination in ground water. MMT was added to gasoline at the maximum allowable level in the United States. Urine was selected because of its significance in toxicological studies. For all samples, good agreement was obtained between the measured and spiked values.

## Introduction

Recent years have seen heightened interest in the investigation of a number of compounds that interfere with the normal action of the endocrine system, collectively known as endocrine disrupting compounds (EDCs). An EDC has been defined as 'an exogenous substance or mixture of substances that alters the function(s) of the endocrine system and consequently causes adverse health effects in an intact organism or its progeny or (sub) population'. Compounds that interfere with the action of endogenous estrogen hormones are known as environmental estrogens, estrogen mimics, estrogenic chemicals, or xenoestrogens.

The significance of these EDCs lies in the biological effects that have been observed in both wildlife and human populations, which have been exposed to them. In wildlife, exposure to elevated levels of environmental estrogens has been associated with sexual disruption of fish populations, eggshell thinning in bird populations, and gonad modification of reptiles. Concern is now focused on the possible implications for humans who have also been exposed to these EDCs, with many of these compounds already implicated in reproductive abnormalities, breast cancer, and male infertility. Compounds identified as priority EDCs include various members of distinct chemical groups such as the bioflavonoids, synthetic estrogens, phenols, alkylphenols, polychlorinated biphenyls, phthalates, brominated flame retardants, organochlorine pesticides, dioxans, and furans. The diverse chemical nature of these compounds is reflected in the diversity of their application, with their widespread use leading to their distribution in various environmental and biological matrices.

In order to appreciate the consequences of exposures to EDCs, it is important to highlight the significance of the endocrine system and of the disruption of its normal function in biological systems.

## The Endocrine System

The body has two important communication systems: (1) the nervous system and (2) the endocrine

system, which regulate and coordinate the activity of the body's muscles and internal organs. A wide range of bodily functions are regulated by the endocrine system, some of which include digestive processes, blood pressure, immune system responses, metabolic rate, and reproductive processes. The major endocrine glands in the body are the hypothalamus and pituitary gland in the brain, the thyroid and parathyroid, the thymus, the adrenal glands, the pancreas, the kidneys, and the gonads (in females the ovaries and in males the testes). The main function of an endocrine gland is to secrete a specific hormone in response to some stimulus, which is generally chemical in nature rather than neural.

The mechanism of action of the steroid hormones is based on a lock-and-key receptor binding procedure. The hormone binds to a complimentary receptor and induced a further cell response. There are, however, additional substances that can interact with the hormone-binding site of the receptor. Such compounds can have agonist, antagonist, or partial agonist activities. Agonists work to mimic the effect of normal hormones through binding to the receptor site and inducing the expected response from the cell. Antagonists block the normal response by binding to the receptor in place of the natural hormone. If the binding is sufficient to prevent binding of the natural hormones then no response will occur. Partial agonists that bind to receptor sites will not induce the full response from the cell but some effect will be observed.

## Estrogens

The estrogen hormones are synthesized in the ovaries in females and in the testes in males. There are at least six distinct estrogen hormones but only three are present in significant amounts in the female body:  $\beta$ -estradiol, estrone, and estriol. All three molecules have a 17-carbon system, which is the steroid with a methyl group at carbon-13 and an aromatic ring with a hydroxyl group at carbon-3.

17 $\beta$ -estradiol is the most biologically active estrogen produced by the ovaries, and is synthesized from androgens by the aromatase complex of enzymes (see Figure 1).

## Androgens

Testosterone is the principal hormone of the androgen group of steroids. Secretion of testosterone

**Figure 1** Chemical structure of three natural estrogens.

increases during puberty and is responsible for the development of male secondary sexual characteristics. In women, androgens are present in the form of androstenedione, which can be converted to testosterone and dihydrotestosterone as needed. Suppression of androgen activity has been seen to improve the survival rate of patients diagnosed with prostate cancer. Antiandrogen treatments are being investigated as therapeutic agents. The synthesis, transport, and metabolism of androgens may be disrupted, by both xenestrogenic and antiandrogenic substances.

Initial research into the area of endocrine disruption focused on the sex steroid hormones, i.e., the estrogens and androgens as several EDCs were found to mimic the action of the natural hormones. Recent research has also included the antiestrogenic and antiandrogenic properties of many of the EDCs. The potential disruption of other hormone signaling systems is also under investigation.

## Endocrine Disrupting Compounds

### Mode of Action

The proposed mode of action of an EDC is to bind to the receptor site in place of the natural hormone. If an EDC succeeds in binding to the hormone receptor it has the potential to activate or block the cellular response characteristic of the hormone it has replaced. Compounds possessing remarkably different structures have been found to compete for the traditional estrogen binding sites on the estrogen receptor and elicit varying degrees of response.

While the molecular structure of EDCs binding to specific receptors can vary greatly, there are often

similarities between these compounds. Many of the estrogen mimicking EDCs share the common structural motif of a phenol or a functional equivalent. They are lipophilic, exhibit resistance to metabolism, and can bioaccumulate.

### Sources of EDCs

Many different types of compounds have been identified as EDCs, all having very different applications. The broad nature of application has resulted in the distribution of these compounds in various environmental and biological matrices and leads to the risk of repeated exposures with compounds originating from different sources. The main sources of exposure to these compounds include the environment, dietary components, and medical and cosmetic products.

Several physicochemical and biological processes determine the concentration, behavior, and ultimate fate of chemical species in the wider environment. Such processes include sorption-desorption, volatilization, and chemical and biological transformations. The chemical characteristics of the compound, including solubility, vapor pressure, and its partition coefficient, will impact upon its residence time in the wider environment.

The aquatic environment acts as a sink for many compounds discharged via the wastewater treatment system. The main input of EDCs to the wider environment is as a result of direct point discharge from both domestic and industrial wastewater treatment facilities. EDCs have been detected in sewage and wastewaters, surface and groundwater, as well as soils and sediments. Conventional wastewater treatment facilities, i.e., those employing primary and secondary treatment technologies, are proving inefficient for the complete removal of all EDCs prior to the discharge of 'treated effluents'. While a significant proportion of the EDCs are retained in the sludge, the stable chemical nature of many of these compounds results in their persistence in the final effluent at low concentrations.

Aside from possible exposure through drinking water sources, dietary exposure to EDCs results from components of diet known as bioflavonoids, phytohormones, or phytoestrogens. These natural plant hormones are less potent than the estrogens found in mammals and in terms of a mass balance approach it has been suggested that the action of such weak or antiestrogens may work to combat the action of elevated environmental estrogen exposure. Some flavones and isoflavones may play an important role in cancer prevention as they are found in plants that are associated with reduced cancer rates.

The use of estrogenic and other hormone-containing preparations in medical and cosmetic applications could constitute another form of exposure to EDCs. One of the main medical applications of the synthetic hormones is in the female contraceptive pill. The detergent nonoxynol, whose main component is nonylphenol (an estrogen mimic), is used as a vaginal lubricant and spermicide.

### Priority Groups of EDCs

Priority groups are estrogens, both natural and synthetic, several phenols, and the polyethoxylated alkylphenol detergents and their breakdown products. Natural estrogens can be considered EDCs after deconjugation restores biological potency. Many of the natural hormones are not removed by conventional wastewater treatment facilities due to their stable chemical composition and resistance to biodegradation (see Figure 2).

Bisphenol-A (BPA) is used in the manufacture of epoxy resins and polycarbonate plastics. These compounds are then used in the manufacture of various other products, including tooth fillings, dental materials, and the coatings on the inside of food tins. BPA was identified as an estrogen mimic after tests with yeast conditioned media (see Figure 3).

Pentachlorophenol (PCP) was introduced in the 1950s and has been included in the list of EDCs. It is used primarily as a biocide for wood preservatives where it is often dissolved in a diesel-type oil and pressure injected into wooden poles (see Figure 4).

Phenolsulfonephthalein, also known as phenol red, is a pH indicator used in tissue culture media. The

compound has been noted to bear a structural resemblance to some nonsteroidal estrogens, such as cyclofenil and chlorotranisene (see Figure 5).

### Alkylphenols

A large number of chemicals known collectively as alkylphenols have exhibited estrogenic behavior and have been identified as components of wastewaters. Alkylphenolic compounds are used in a variety of applications. The alkylphenols octylphenol and nonylphenol are used as antioxidants in plastics. Both nonylphenol and octylphenol have been identified as estrogen mimics using vitellogenin gene expression in trout hepatocytes, gene transcription in transfected cells, and by the growth of breast cancer cell lines (see Figure 6).

Both octylphenol and nonylphenol are found in the wider environment as a result of the biodegradation of the alkylphenolic polyethoxylates (APEOs) and are themselves recalcitrant breakdown products. The nonionic alkylphenol ethoxylated surfactants, namely

**Figure 3** Chemical structure of bisphenol-A.

**Figure 4** Chemical structure of pentachlorophenol.

**Figure 2** Chemical structures of synthetic estrogens: (A) diethylstilbestrol and (B) ethynylestradiol.

**Figure 5** Chemical structure of phenolsulfonephthalein (phenol red).

**Figure 6** Chemical structures of (A) octylphenol and (B) nonylphenol.

octylphenol ethoxylate and nonylphenol ethoxylate, are found in domestic and industrial products with some of the applications including shampoos, some detergent-containing petrol, and pesticides formulations. Their structure consists of an alkylphenol with a side chain of several ethoxylate groups, ranging from 2 to 20 units. The biotransformation of the APEOs to the parent alkylphenols involves hydrophilic attack of the ethoxylate chain, which is progressively shortened by one ethoxylate group at a time.

## Determination of EDCs in the Aquatic Environment

The analysis and identification of estrogen-mimicking EDCs is generally achieved using a combination of biological assays and analytical separation techniques. The biological potency of a compound can be assessed using *in vivo* or *in vitro* assays and activity is usually expressed relative to that of estradiol, which is the most common endogenous estrogen.

Chromatographic methods are routinely used for the analysis of environmental estrogens due to their tailored selectivity and high resolving power resulting in efficient analyses. Coupling of chromatography-based separation techniques to sensitive detection methods has allowed the qualitative and quantitative measurement of target analytes in complex matrices. The automation of many devices also allows for continuous analyses and increased sample throughput while the modular design of some systems allows online coupling to pre-separation preparatory units.

Due to the significant interest in the development of analytical techniques for the determination of EDCs in a variety of matrices, several reviews of analytical methodologies used have been published recently.

### Biological Assays

Various biological assays can be employed in order to determine the potency of the compound under investigation. The main methods used for the analysis of xenostrogens have been summarized previously. The techniques can be classified according to biological complexity.

**Receptor binding assays** Receptor binding assays are easy to perform, and allow identification of both agonists and antagonists acting through the receptor but are unable to differentiate the binding of agonists or antagonists. By measuring the direct binding of the chemicals to the fish estrogen receptor can assess the estrogenicity of a selection of environmentally persistent chemicals.

**DNA binding assays** DNA binding of the estrogen receptor only occurs when the hormone-binding sites are occupied by suitable ligands. The kinetics of human estrogen receptor binding to its specific DNA element can be measured using a BIAcore biosensor system.

**Receptor gene assays** The yeast estrogen screen assay has been widely used for the determination of the estrogenic potency of many compounds. It is based on the introduction of two genes into yeast, one of which expresses the estrogen receptor and a reporter plasmid containing a gene coupled to the estrogen response element. The binding of an estrogen or estrogen mimic to the receptor results in the subsequent binding of the complex to the DNA estrogen response element facilitating the expression of  $\beta$ -galactosidase. The resulting enzyme activity can be measured by conversion of a substrate to nitrophenol, which is then detected. While the assay can take a day to complete, it has the advantage of simulating biological effects including the membrane passage of active components.

### Proliferation of estrogen-sensitive cells (E-screen)

Breast cancer cell lines are known to proliferate in response to estrogen stimulation. Charcoal-dextran stripped human serum inhibits the proliferation of MCF-7 breast cancer cells in a dose-dependant fashion. Estrogens overcome this effect. The E-screen test exploits the estrogen-dependant proliferation of MCF-7 cells and has been used previously for the determination of the estrogenic potential of phenol red, estradiol, and tamoxifen among other compounds. Such assays can take 4–7 days.

**Biomarkers** The observation of biological responses can also be used as an indication of EDC exposure. In studies where fish have been exposed to sewage the results have indicated that sewage effluent was estrogenic in nature. Exposed fish experienced a rapid and pronounced increase in their plasma vitellogenin concentrations. Rainbow trout and wild roach populations from various river sites have shown evidence of vitellogenin induction. Quantification of

vitellogenin concentrations can be achieved using an established homologous carp radioimmunoassay.

## Sample Preparation Techniques

EDCs in the aquatic environment are often present in complex matrices such as effluent samples. For this reason, wide ranges of sample preparation and pre-concentration techniques have been employed in conjunction with analytical separations. Preconcentration is often necessary due to sensitivity limitations of the instrumental techniques.

Solid-phase extraction (SPE) has been used in conjunction with separation techniques [gas chromatography (GC), liquid chromatography (LC), and capillary electrophoresis (CE)] for environmental analysis. Recent developments in both SPE and solid-phase microextraction (SPME) have been reviewed. Some of the solid phases investigated previously include graphitized carbon black, octadecylsilica, and C<sub>18</sub> cartridges. Comparisons of the sorbent materials available for the extraction of phenols have been carried out in conjunction with chromatographic separations. A comparison of polycrystalline graphites and SPME fibers [poly(dimethyl siloxane/divinylbenzene), carbowax] showed that both performed equally well for the extraction of nonionic surfactants. SPME fibers have been used in the analysis of short-ethoxy-chain nonylphenols in raw and treated water recently. Semipermeable membrane devices have been used for the identification of a number of hydrophobic organic contaminants.

Additional sample preparation techniques investigated for EDCs include supercritical fluid extractions with the addition of modifiers to aid compound solubility. Extractions of organic compounds can also be accelerated using microwave energy.

## Liquid Chromatography

LC has been used extensively for the determination of many EDCs due to the many favorable aspects of the technique. Some advantages of LC separation systems for the determination of EDCs include:

- good separation efficiency and selectivity;
- nonvolatile analyte separation;
- compatibility with sensitive detection modes; and
- online sample cleanup.

This technique can achieve efficient separations of polar and nonpolar analytes through the variation of both the stationary and mobile phases allowing variation of separation selectivity. LC has been applied to the determination of several phenolic

endocrine disrupting compounds in real samples. Up to 28 phenolic compounds have been separated in a single run using a C<sub>18</sub> stationary phase. Reversed-phase LC has been applied to the determination of BPA and phenol. Isocratic LC has been used for the determination of the 11 priority pollutant phenols, which include phenol, PCP, 2,4,6-trichlorophenol, and several other nitro- and chloro-phenolic compounds. The use of specialized chiral stationary phases can further alter the selectivity of LC methods.  $\beta$ -Cyclodextrin stationary phases have been applied to the analysis of several estrogens, both natural and synthetic forms.

As the system is aqueous based, it is routinely used for the analysis of nonvolatile analytes with no need for derivatization of sample to maintain analyte solubility. A typical LC system experiences lower diffusion rates than GC because the mobile phase has a higher viscosity and density. LC can be coupled online to sensitive electrochemical and fluorescence detection units. This is an important consideration for the analysis of EDCs present at low concentrations in environmental matrices. Both UV and EC detection were applied to the determination of estrogenic compounds in water samples using LC.

Pre- and guard columns can be used for online sample cleanup in conjunction with LC, which helps maintain sample integrity while protecting expensive and fragile stationary phases. Samples may also be preconcentrated prior to elution onto separation column.

The interfacing of LC systems to mass spectrometric (MS) detection units has also allowed further detection strategies. Normal-phase LC with electrospray mass spectrometric detection has been employed for the determination of alkylphenols, including nonylphenol ethoxylates in the aquatic environment and BPA in biological fluids and environmental samples.

Fluorescence detection has also been employed for the detection of estrogens, concentrations of octylphenol and nonylphenol ethoxylates in effluent samples among others. Derivatization can allow the selective detection of analytes when interfering compounds may be present in the sample. Derivatizing agents including 2-(4-carboxyphenyl)-5,6-dimethylbenzimidazole and dansyl chloride have been used.

Conventional methods have more recently been coupled to biological-based assays in order to improve the sensitivity and selectivity of conventional techniques; for example, LC coupled online to receptor affinity detection based on the human estrogen receptor.

The disadvantages of LC systems for the analysis of EDCs include:

- high reagent and sample consumption and
- limited detector compatibility.

LC systems also tend to have a large sample capacity combined with higher solvent demands in the liters per day range as opposed to CE where it is milliliters per day. The large solvent demands of the system lead to increased consumption of expensive chemicals and increased waste for disposal.

The organic nature of both analytes and mobile phases limits detection modes to those that can differentiate between the two. The fragile nature of many of the stationary phase packed columns can lead to further expense in terms of installation, method development, and replacement.

The use of gradient elution methods is often necessary to allow the analysis of analytes of differing polarities, as is the case with mixtures of EDCs, many of which exhibit poor solubility in aqueous systems due to their hydrophobic nature. While gradient schemes can be automated with suitable instrumentation, this adds to the complexity of the separation.

## Gas Chromatography

GC has also been employed extensively for the determination of several EDCs.

The advantages of GC separation systems for the analysis of EDCs include:

- good separation efficiency and selectivity;
- small sample and reagent demands; and
- compatibility with sensitive detection modes.

GC analysis can achieve a high degree of analyte resolution and peak efficiency when long columns are employed. Separation selectivity can be altered by the variation of the stationary phase. This technique is less complex than either CE or LC resulting in straightforward method development options. As with CE methods, GC analysis only demands small sample volumes, which is an advantage when working with toxic or expensive compounds. There is no mobile phase, buffer preparation, or solvent waste to deal with using a GC system. GC methods have been applied to the determination of several phenolic EDCs including BPA and Bisphenol F.

GC has been applied to the determination of several alkylphenols. The determination of 4-nonylphenol (4-NP) in effluent and sludge from sewage treatment plants has been shown while alkylphenol ethoxylates have been determined in industrial and environmental samples using GC–MS.

GC is readily coupled to MS detection, which provides the sensitivity needed to allow quantification of environmental and biological levels of environmental estrogens in real samples, which are often present in the low  $\text{ng l}^{-1}$  to  $\mu\text{g l}^{-1}$  range.

Nonylphenol polyethoxylates and their degradation products have been detected in river water and sewage effluent by GC–ion trap (tandem) MS with electron impact (EI) and chemical ionization, which was followed by direct GC–MS analysis in EI–MS, chemical ionization mass spectrometry (CIMS), or CIMS–MS modes.

While many methods use offline preconcentration methods, SPME has been used for estrogens and anabolic steroids with on-fiber derivatization prior to analysis by GC–MS analysis (see Figure 7).

The disadvantages of GC systems for the analysis of EDCs include:

- limited to analysis of compatible analytes and
- limited method optimization options.

GC analyses are best suited to those analytes that have significant vapor pressure, are thermally stable at operating temperature, and have molecular weights of less than 1000. Compounds such as the lower chain alkylphenols are difficult to separate using GC due to their reduced volatilities. The polar nature of the extended ethoxylate chains of parent detergent compounds is also an issue.

Temperature programming can aid the separation of some analytes with faster separation at high

**Figure 7** Determination of priority EDCs using GC–MS in scan mode. Temperature ramp conditions –  $80^{\circ}\text{C min}^{-1}$ ; ramp –  $8\text{--}150^{\circ}\text{C}$  (150 for 8 min); ramp –  $11\text{--}280^{\circ}\text{C}$  (280 for 5 min). Peak identification: 1. phenol; 2. ethylphenol; 3. dichlorophenol; 4. 4-propylphenol; 5. 2-sec-butylphenol; 6. 2,4,5-trichlorophenol; 7. biphenyl; 8. methylparaben; 9. 2,3-tertbutyl-4-hydroxyanisole; 10. 4-hexyloxyphenol; 11. hexachlorobenzene; 12. pentachlorophenol; 13. lindane; 14. octylphenol; 15. 4-heptyloxyphenol; 16. octylphenol 2-polyethoxylate; 17. nonylphenol; 18. nonylphenol 2-polyethoxylate; 19. bisphenol A; 20. dieldrin; 21. DES; 22. estrone; 23.  $17\beta$ -estradiol; 24. ethynyl estradiol; 25. NP 12 polyethoxylate. Unlabeled peaks due to column bleed.

**Table 1** A comparison of a GC–MS method and a CE method (in the micellar electrokinetic chromatography (MEKC) mode) for the separation of priority endocrine disruptors. Resolution and limit of detection (LOD) are used as parameters for comparison

<i>Synthetic estrogens (in order of migration)</i>	<i>Resolution with MEKC</i>	<i>LOD (mg l<sup>-1</sup>)</i>	<i>Synthetic estrogens (in order of migration)</i>	<i>Resolution with GC/MS</i>	<i>LOD (mg l<sup>-1</sup>)</i>
Estriol	0	7.2	Phenol	0	0.2
Phenol	12.5	2.0	Butylphenol	20.0	1.0
Trichlorophenol	1.8	4.9	Trichlorophenol	4.2	0.08
Bisphenol-A	2.1	4.0	Biphenyl	1.1	0.05
PCP	0.9	6.7	Nonylphenol	–	0.02
Butylphenol	1.6	3.8	PCP	62.7	0.04
Estrone	7.7	6.8	Bisphenol-A	16.4	0.02
17 $\beta$ -estradiol	5.8	6.8	DES	7.0	1.0

Ethinylestradiol	4.2	7.4	Estrone	0.6	2.0
Nonylphenol	36.5	5.5	Ethinylestradiol	2.0	5.0
			Estriol	5.0	20.0

temperatures offset by increased analysis times. The majority of separations of EDCs with GC employed some form of analyte derivatization procedure in order to achieve detection limits required. A separation of EDCs was achieved without derivatization, however, using online SPE and GC–MS–MS. While GC separations are less complex than LC and CE separations, method development options are limited as stationary phase and temperature are two of the main variables in the separation. Variation of often-fragile stationary phases can be expensive (see Table 1).

### Capillary Electrophoresis

Despite the routine use of GC–MS and LC for the analysis of EDCs there is another analytical technique that has potential for the analysis of these compounds. CE, though not without its own limitations, offers some advantages over existing techniques, which are outlined below:

- good separation efficiency and selectivity;
- method optimization options;
- low sample and reagent consumption;
- wide range of analyte application;
- miniaturization; and
- compatibility with sensitive detection modes.

One of the main advantages that CE offers over existing analytical methods is its ability to efficiently resolve both neutral and charged analytes in a single run. The selectivity of the analysis can be altered through the addition of various components to the run buffer system. These would include organic solutions to aid solubility of hydrophobic compounds, surfactants, and other agents designed to alter the solubility and migration characteristics of the analytes under investigation. The more recently developed technique of capillary electrokinetic chromatography

(CEC), which has been described as a combination of CE and chromatography, would potentially allow an efficient analysis of the environmental estrogens as extremely high peak efficiencies are a characteristic of this technique. CEC is still in the early stages of development, however, with the only alternative to expensive commercial columns involving difficult packing procedures for home-built systems.

CE method development options are cost-effective and simply involve the direct addition of agents to run buffer. The low cost of capillaries allows dedication of individual capillaries to specific methods, which aids reproducibility. This is another advantage of this technique that minimizes the cost of method development and waste generated. CE systems have small sample and reagent demands, which is a definite advantage when working with expensive or hazardous materials. As CE can be used for the separation of a broad spectrum of analytes including polar and nonpolar compounds, there is no need for derivatization to improve compound solubility, as is the case with some GC applications. Hydrophobic analytes can also be separated through the modification of traditional CE buffer systems. Nonaqueous CE modes allow separation of compounds in organic solvents as opposed to aqueous buffers.

There are, however, certain limitations to the technique for the analysis of EDCs including:

- sensitivity of commercial detectors available and
- complexity of separations and reproducibility.

The limited light path and low sample injection volumes further reduce the detection sensitivity of the system. While method development is relatively simple, the addition of agents to the run buffer system alters the complexity of the separation by increasing the number of variables. The presence of

multiple separation components can also influence the reproducibility of the separation. Fluorescence detection and mass spectrometric detection are seeing some use with CE. Analytical applications of these detection techniques with CE are in the early stages of development.

### Introduction

Environmental analysis encompasses matrices from the hydrosphere, atmosphere, lithosphere, and biosphere, and target analytes include naturally occurring chemicals and anthropogenically derived contaminants. In many environmental situations it is important to determine fluxes, which are time integrated loads, as well as concentrations. Particular challenges include the extremely low concentrations of many individual chemicals, the different physicochemical forms of elements (e.g., redox state,

complexed, dissolved, particulate, and colloidal fractions), the heterogeneity of sampling locations, the scale of temporal and spatial variability, access to sampling sites, and the potential instability of stored samples due to factors such as biological activity, atmospheric contamination, and chemical reactivity. Key drivers for environmental analysis are legislation for monitoring anthropogenically derived chemicals, both at the point of emission/discharge and in receiving atmospheres/waters and the need to better understand environmental processes in both pristine and impacted environments. The interface between chemistry and biology is an increasingly important aspect of environmental science in areas such as ecotoxicology, human and ecosystem health, and terrestrial/aquatic ecology and they all require high-quality chemical measurements.

multiple separation components can also influence the reproducibility of the separation. Fluorescence detection and mass spectrometric detection are seeing some use with CE. Analytical applications of these detection techniques with CE are in the early stages of development.

### Introduction

Environmental analysis encompasses matrices from the hydrosphere, atmosphere, lithosphere, and biosphere, and target analytes include naturally occurring chemicals and anthropogenically derived contaminants. In many environmental situations it is important to determine fluxes, which are time integrated loads, as well as concentrations. Particular challenges include the extremely low concentrations of many individual chemicals, the different physicochemical forms of elements (e.g., redox state,

complexed, dissolved, particulate, and colloidal fractions), the heterogeneity of sampling locations, the scale of temporal and spatial variability, access to sampling sites, and the potential instability of stored samples due to factors such as biological activity, atmospheric contamination, and chemical reactivity. Key drivers for environmental analysis are legislation for monitoring anthropogenically derived chemicals, both at the point of emission/discharge and in receiving atmospheres/waters and the need to better understand environmental processes in both pristine and impacted environments. The interface between chemistry and biology is an increasingly important aspect of environmental science in areas such as ecotoxicology, human and ecosystem health, and terrestrial/aquatic ecology and they all require high-quality chemical measurements.

## Environmental Legislation

Environmental protection is a global issue with a plethora of protective legislation, enacted as transnational and national regulations and guidelines, aimed at sustainable use of water, soil, air, and biomass. These laws apply not only to the polluter but also to governments, national institutions, and individuals. They are designed to protect human health and ecosystems from the effects of chemical contaminants, to guarantee the quality of natural resources, e.g., potable water and to facilitate the recovery of degraded environments, e.g., contaminated land.

Within Europe, European Council Directives and Regulations form an overarching legislative framework that requires Member States to take preventative action and specifies that environmental damage should, as a priority, be rectified at source and that the polluter should pay. Importantly, environmental protection is also required to be integrated into other European Community (EC) policies, emphasizing its pervasive nature. Thus, Member States have a strong impetus to enact environmental legislation that incorporates the concepts of responsibility and control. Directives formally bind Member States and specify the outcomes and deadlines but the exact form of the legislation is at the discretion of the individual member country. However, delays in implementation have led to the increased use of EC regulations that bind individual states directly, without requiring national implementation. The principles of subsidiarity and harmonization also apply to environmental law within the EC. Individual Member States have responsibility for enforcement, although overall policing is by the EC and, increasingly, by the European Environment Agency (EEA) and the European Court of Justice.

Within the UK, environmental protection is embodied in overarching statutes, e.g., the Environmental Protection Acts of 1990 and 1995, which require both an integrated approach, as embodied in the European Community Water Framework Directive, and a precautionary approach, as embodied in the 1999 Pollution Prevention and Control Act. Statutes are supported by Government Circulars and statements of policy, codes of practice, and orders and policies from agencies such as the Environment Agency and the Health and Safety Executive.

In the USA, 12 major statutes covering, e.g., Pollution Prevention, Clean Air, Clean Water, and Toxic Substances form the basis of an overarching legislative environmental protection policy generally administered by the US Environmental Protection Agency (EPA). The statutes either set, or require to

be set by the EPA, emission, quality, discharge, disposal, and testing standards with the intention of safeguarding the environment while enabling economic and social development.

International agreements and conventions, e.g., OSPAR and the Rio Summit, define a framework for transnational cooperation on many environmental issues such as sustainable development, biodiversity, protection of endangered species, tropical rain forests, the ozone layer, and means to combat global warming. The establishment of, and compliance with, environmental protection legislation/policies provides a major driving force for many analytical science developments. There is a demonstrable need for highly accurate and precise analytical techniques with increasingly low detection limits for an increasing number of chemicals. This has given impetus to the development of novel environmental analytical methodologies, clean sampling and analytical protocols, and continuous/*in situ* monitors.

## Sampling

Reliable sampling is a key first step in any analytical program. Samples should be representative of the bulk medium from which they are taken and should not change in composition between collection and analysis. Care must therefore be taken to avoid contamination of the sample, e.g., from the atmosphere or the addition of reagents, and loss of analyte, e.g., by volatilization, adsorption, or biological transformation. Sample containers should be non-contaminating, for example, when collecting water samples the use of high density polyethylene for trace metals and glass for organic compounds is recommended. Containers should also be thoroughly cleaned with appropriate solvents before use to prevent contamination. When designing a sampling program, the temporal and spatial variability of environmental samples must also be considered, together with cost, time required, and safety issues. Ultimately the design of the sampling program will depend on the issue that is being addressed. Examples of temporal variability include diurnal cycles, tidal cycles, seasonal trends, and transient human impacts. Spatial variability is often due to point source inputs, such as a sewage treatment works outfall or a stack emission, and mixing processes, e.g., where a tributary joins a river or where air masses converge. The addition of chemicals to the sample at the point of collection, such as chloroform to minimize biological activity and acid to minimize adsorption on the walls of the container, is often required, especially if the sample is stored for some time prior to analysis. However, such additions can

introduce contamination and alter the speciation of the analyte.

## Analytical Techniques

Many 'baseline' environmental measurements, e.g., pH, Eh, conductivity, dissolved oxygen, temperature, flow rate, and turbidity for water samples, can be acquired in the field using simple, cheap, and robust handheld instrumentation. However, most chemical determinands require sampling followed by laboratory analysis.

Many organic and inorganic determinants in environmental matrices require separation and pre-concentration (if concentrations are below instrumental detection limits) prior to detection. This can be done by solvent extraction or solid-phase extraction using selective adsorbents, ion-exchange resins, or chelating resins. In many applications, however, chromatographic techniques with higher resolving power are needed. Gas chromatography (GC) for example, particularly in combination with mass spectrometric detection (GC-MS), is widely used for separating and quantifying individual organic compounds in air, water, and biological matrices. Liquid chromatography (LC), also in combination with MS (LC-MS), is particularly useful for determining low volatility compounds at room temperature, thus minimizing sample decomposition. More recently, capillary electrophoresis (CE) with ultraviolet (UV diode array) or fluorescence detection has been used for rapid and highly efficient separation and quantification of environmental samples.

Atomic spectrometric techniques such as flame atomic absorption spectrometry (FAAS), electrothermal AAS (ETAAS), inductively coupled plasma atomic emission spectrometry (ICP-AES), and ICP-MS are used for the determination of elements, particularly metals. ICP-MS is the most sensitive, typically with microgram per liter detection limits and multielement capability but it has high start-up and operating costs. UV-visible spectrophotometry is also used for the determination of metal ions and anions such as nitrate and phosphate (usually by selective derivatization). It is a low cost and straightforward technique, and portable (handheld) instruments are available for field deployment. Flow injection (FI) provides a highly reproducible means of manipulating solution chemistry in a contamination free environment, and is often used for sample manipulation, e.g., derivatization, dilution, preconcentration and matrix removal, in conjunction with spectrometric detection. Electroanalytical techniques, particularly voltammetry and ion-selective electrodes (ISEs), are

also used for the determination of metal ions in solution. Anodic stripping voltammetry (ASV) and cathodic stripping voltammetry (CSV) are very sensitive and provide data on elemental speciation, whereas ISEs are small, portable, and low-cost sensors that can also be deployed outside the laboratory.

Biological monitoring techniques such as immunoassays are now available for environmental analysis. These form the basis of low cost, rapid, and highly selective kits for the determination of specific compounds or classes of compounds, such as polyaromatic hydrocarbons, polychlorinated biphenyls, pesticides, herbicides, and insecticides, in food, water, and soil matrices. They are simple to use and are well suited to screening sites for contamination prior to sampling and laboratory analysis. Immunoassays can also be applied to blood and urine samples for assessing the exposure of organisms to contaminants.

## Speciation

Legislatively defined chemical exposure limits and quality guidelines often refer to total concentrations of an element. Speciation, however, refers to the specific physicochemical forms of an element that together make up the total metal concentration. Determination of particular chemical forms of an element can provide a much better indicator of bioavailability, toxicity, and mobility than total element concentration. For example, inorganic forms of arsenic are very toxic, whereas arsenobetaine, the form of arsenic found in aquatic organisms, is not. Conversely tributyltin (an antifouling agent) is much more toxic than inorganic tin species. Factors such as pH, redox potential, and particulate/colloidal matter influence the speciation of elements in environmental systems. For example, aluminum and other metals are leached from soils by acid rain due to their higher solubility at low pH. From an analytical perspective the determination of specific physicochemical forms of an element is particularly challenging due to their lower concentrations compared with the total element, and the enhanced selectivity required.

## Continuous Monitoring

Advances in instrumentation and communications (for data transmission) have increased the reliability of continuous monitors. Such systems can be deployed in remote and hazardous locations to provide high temporal resolution chemical data in aquatic and atmospheric environments. Examples include sensors for monitoring nutrients in rivers, instrumented buoys for oceanographic mapping, and

spectroscopic techniques for monitoring stack gas emissions.

## Quality Assurance and Data Handling

Environmental analytical data is often used as a tool for making environmental management decisions or for legislative compliance/enforcement and, therefore, good quality assurance (QA) is essential. This includes the periodic use of performance audits to ensure good laboratory practice, participation in interlaboratory comparison exercises, use of certified reference materials to assess accuracy, determination of blanks, and replicate analyses to assess precision (expressed as relative standard deviation). Regression analysis is often applied to environmental datasets, and tests for outlier rejection (e.g., Grubbs test) are also used. Techniques such as analysis of variance (ANOVA) can be used to assign and compare different sources of variability in a dataset and are therefore useful for separating analytical variability from real environmental differences. Chemometric techniques, e.g., principle component analysis (PCA), are particularly suited for investigating relationships between variables in large datasets such as those generated by environmental monitoring programs. It is essential with such datasets that the information is demonstrably reliable, i.e., statistically robust, before using them for environmental interpretation.

## Safety

Risks to persons or to the environment must be minimized by adherence to safety legislation and protocols, e.g., Occupational Health and Safety (COSSH in the UK), which informs on health risks associated with specific chemicals and appropriate medical and cleanup procedures in the event of exposure or a spillage. Before undertaking field work, a site-specific risk assessment should be carried out to identify potential risks and specify safe practices. Important issues include transport of personnel and equipment, weather conditions, possible health risks from the sample and the general environment, appropriate protective clothing, safe onsite working practices, safe use of equipment, communications, and emergency procedures.

## Air

Monitoring the natural components of air, and of emissions into it, is of global importance due to the need for clean air for respiration and the potential long-range transport of pollutants. For example,

transnational-boundary SO<sub>2</sub> emissions from fossil-fuel-fired power stations can acidify rain that in turn acidifies lakes and rivers, solubilizes metals, and reduces biodiversity. Naturally occurring but anthropogenically enhanced climate change gases, such as CO<sub>2</sub> and CH<sub>4</sub>, as well as stratospheric ozone that protects against damaging UV radiation, also require global monitoring. Air is often analyzed for legislative compliance, e.g., Air Quality Limit Values (AQLVs) and for human exposure limits to toxic gases such as benzene, especially those occurring indoors or in the workplace. Ground level ozone (a plant growth inhibitor) and oxides of nitrogen from combustion engines contribute to smog formation and impact on human health concerns such as asthma. They are therefore also routinely monitored.

## Sampling

Sampling is a critical aspect of the analytical process due to the dynamic nature of atmospheric environments, which result from chemical reactivity, rapid dispersion, and spatial/temporal variability. Accurate measurement of the volume of air sampled, sampling time, and location are important factors. The choice of extractive (onto solids or into liquids) or passive sampling is often dictated by the analyte. Passive sampling is unsuitable for labile atmospheric substances due to their reactivity and adsorption onto container walls; most reactive gases can only be measured *in situ*. However, volatile organic compounds (VOCs) are often sampled by extractive filtration, followed by GC-MS analysis. Most extractive samplers operate for 8–24 h to enable averaging over a suitable time period. There are also specialist sampling methods for aerosols, often with a focus on sub 10 µm (PM<sub>10</sub>) and especially sub 2.5 µm (PM<sub>2.5</sub>) particulates due to their penetration into the respiratory tract and alveoli of lungs.

## Analytical Techniques for Air

There are a number of techniques that can be used in the field. These include electrochemical sensors for gases such as O<sub>2</sub> and SO<sub>2</sub> and diffusive samplers containing immobilized reagents that produce a visible color change with visual detection on exposure to a specific chemical. Passive diffusion tubes can also be used for analyte preconcentration. Subsequent laboratory analysis is usually undertaken by thermal desorption coupled with GC. This approach is particularly useful for trace organic compounds such as polyaromatic hydrocarbons (PAHs) and VOCs. Spectrometric techniques such as Fourier transform infrared (FTIR) spectrometry, correlation spectrometry, and the laser based LIDAR (light detection

and ranging) are sophisticated instrumental techniques that can be transported in a mobile laboratory and used for large-scale remote mapping, e.g., of plumes emitted from a power station or factory stack.

## Waters

The oceans make up 97% of the world's water, with 2.5% present as freshwater. Of this, 75% is in the form of glaciers, 24% is groundwater, and only 1% is in rivers, lakes, and soils. Environmental analysis encompasses all of these different water types as well as dynamic interfacial regions such as estuaries (0–35% salinity), potable waters, waste waters, and interstitial waters. Marine waters include areas of high primary biomass productivity, e.g., coastal and shelf waters, which are often rich in macronutrients (nitrate and phosphate) and metals (from riverine and short-range atmospheric deposition). The water column is usually stratified with a shallow, well mixed upper layer (euphotic zone) and has distinct seasonal influences. Open ocean environments are characterized by less well-differentiated waters, e.g., central gyres, that have a deeper euphotic zone, and for a number of elemental constituents are strongly influenced by long-range atmospheric deposition.

The availability of suitable quantities of high-quality freshwater, when required and in the right location, is a major global environmental issue. National and transnational water management policies should, therefore, be knowledge based and designed to sustain, protect, and enhance waters while maintaining economic, e.g., fisheries or agriculture, and social use, e.g., drinking water, recreational activity, and visual amenity. Within Europe, for example, the 2000 Water Framework Directive provides a comprehensive legal and management framework for an integrated and coordinated approach to sustainable water management rather than using single chemical indicators of water quality such as dissolved oxygen.

## Sample Preservation

It is essential to preserve the integrity of the sample between the time of collection and the time of analysis. There are, however, several processes that can cause changes in the chemical composition. Examples of these include biodegradation (e.g., of nitrogen- and phosphorus-containing compounds), oxidation (e.g., of Fe(II) and organic compounds), absorption (e.g., of CO<sub>2</sub> which affects pH and alkalinity), precipitation (e.g., removal of CaCO<sub>3</sub>, Al(OH)<sub>3</sub>), volatilization (e.g., loss of NH<sub>3</sub>, HCN), and adsorption (e.g., of dissolved metals on the walls of the container).

Changes in composition can be retarded, but not prevented, by refrigeration at  $-4^{\circ}\text{C}$  (which reduces biological activity), freezing at  $-20^{\circ}\text{C}$  (but only for plastic bottles), addition of preserving agents at the point of sampling (e.g., acidification for trace metals, biocides such as HgCl<sub>2</sub>) for biodegradable determinants), and filtration (to remove biotic and abiotic particulate matter but not all bacteria and viruses). Commonly filtration through a 0.45 or 0.2- $\mu\text{m}$  filter (cellulose acetate or polycarbonate) is used to operationally separate the 'dissolved' from the 'particulate' fraction. However, this is not appropriate for separating the 'colloidal' fraction and for this fractionation techniques such as field-flow fractionation can be used.

## Analytical Techniques for Waters

Freshwater and seawater pose different analytical challenges. Matrix effects (enhancing or quenching interferences) are usually greater in seawater, e.g., dissolved solids coating out on ICP cones, or the Schlieren (refractive index) effect in flow-through analyzers with molecular spectroscopic detection, such as in the determination of phosphate using the molybdenum blue chemistry. Dissolved organic matter (DOM) is often complexed with metal ions in natural waters and this can mask their detection to varying degrees with different detectors. Atomic spectroscopic techniques generally determine total metal concentrations, whereas techniques such as voltammetry only determine the electroactive forms of the element.

Physicochemical indicators such as pH, Eh, conductivity, dissolved oxygen, temperature, light, and nutrients are the 'master variables' for water quality and can be determined in the field using portable (handheld) instrumentation. More sophisticated instrumentation is required for other parameters such as trace metals, organic compounds, and generic parameters such as chemical oxygen demand (COD) and biological oxygen demand (BOD). Each class of aquatic elements/compounds poses its own analytical challenges. Organic substances can be separated from matrix interferences by solvent extraction followed by back-extraction into a suitable medium, e.g., nitric acid. Volatile organic compounds can be separated by automated solid-phase microextraction (SPME) or purge-and-trap techniques. GC-MS is commonly used for screening and quantifying organic compounds due to its high specificity and sensitivity.

Trace metals in waters are commonly determined by atomic spectrometry (FAAS, ETAAS, derivatization (hydride/cold vapor), AAS, ICP-AES, and ICP-MS),

voltammetry (CSV and ASV), and flow injection (FI) with molecular spectroscopic detection. It is also possible to predict water quality using biological monitoring techniques to evaluate the interaction between environmental factors and physiological processes operating at different scales. *In situ* analysis using portable instrumentation enables the collection of near real-time data, provides high temporal and/or spatial resolution, and minimizes the need for sample preservation, storage, and transport. Reliable monitors can also reduce the cost of surveillance programs.

## Soils and Sediments

Soils and sediments are important reservoirs in the lithosphere, acting as sinks and sources for many chemical species. Soils are a key component of both natural and agricultural terrestrial ecosystems and are essential for the growth of plants and the degradation and recycling of biomass. They are highly variable but can be broadly characterized by soil texture and hence classified by particle-size distribution into sand (coarse) and silt and clay (fine) fractions. Key soil properties that define its chemical behavior include pH, content of organic matter, mineralogy (aluminosilicates and oxides of iron, manganese, and aluminum), cation exchange capacity, and its three-dimensional structure. Soils also contain water, air, and living biota and can be vertically subdivided into layers or horizons through a soil profile. These consist of an uppermost organic rich, leaf litter layer (L layer or O horizon), overlying an eluvial mineral/organic A horizon from which materials are generally washed downward, an illuvial B horizon of altered parent material in which materials accumulate and a C horizon which is the parent material. If unweathered rock is present below the C horizon it is known as bedrock (R layer).

Sediments are the particulate solid material that accumulates beneath aquatic environments and can be broadly classified into three types. Lithogenous sediments, which are produced directly from the disintegration of preexisting rocks and volcanic debris; biogenic sediments that are the remains of organisms; and hydrogenous sediments formed by *in situ* chemical reactions, e.g., precipitates from seawater. Sedimentary biogeochemistry is therefore determined by lithological composition and by hydrological, biological, geological, and anthropogenic influences. Sediment chemicals can be remobilized through dredging activities or changes in physicochemical parameters such as bottom water currents, pH, or dissolved oxygen concentration. For example Cu, Cd, and Zn can be remobilized by oxidation of the

sulfidic phases and organic matter in contaminated, anoxic benthic sediments. Aquatic systems with high particulate loading such as turbid estuaries can also impact significantly on sediment biogeochemistry.

## Extraction Techniques

The simplest sediment/soil extraction technique involves mixing (e.g., shaking or ultrasonic blending) with an appropriate solvent at room temperature, followed by filtration or centrifugation. For non- and semipolar organic compounds Soxhlet extraction is often used but thorough wetting of the soil/sediment is essential to obtain an efficient extraction. Column extraction using an appropriate solvent and supercritical fluid extraction (SFE) are also used. SFE requires less material and time, and offers a more selective extraction by alteration of the extraction temperature and/or pressure, or the use of modifiers. Since the extraction temperatures are relatively low, thermally labile components are protected from decomposition. As the supercritical fluids used for extraction are gases at ambient temperature, a concentration step after extraction is not required. Volatile organic compounds in soil can be extracted by purge-and-trap or headspace analysis, which provide a matrix free sample for analysis.

For the extraction of metals, sequential extraction schemes such as 'Tessier' and 'BCR' are often used. This approach mimics various natural conditions under which elements are released from sediments and soils. The BCR scheme extracts sequentially with (1) acetic acid (mild acid), (2) hydroxylamine hydrochloride (reducing agent), and (3) hydrogen peroxide and ammonium acetate (oxidizing agent). Each stage is interspersed with centrifugation and washing of the sample to give three extracted fractions. The Tessier scheme (five stages) has been used to separate, for example, the components of coal ash resulting from coal-fired power generation (distilled water for the adsorbed fraction, ammonium acetate for the ion exchangeable fraction, ammonium oxalate/oxalic acid for the oxyhydroxides of iron, manganese, and some aluminosilicates, acidic  $H_2O_2$  for the organic fraction, and concentrated HCl for the remainder of the aluminosilicates). A simple approach to determine the 'bioavailable' fraction of a soil or sediment is extraction with a dilute acid to mimic the pH of the stomach. Sequential extraction has also been used to enable metabolic profiling of plant tissues by separating plant metabolites with similar properties, e.g., using water for salts, amino acids, carbohydrates, and organic acids, methanol for phenolics, flavonoids, and other polar organic compounds, and chloroform for lipids and terpenes.

## Introduction

Living systems rely on kinetic stability for their existence. They are all thermodynamically unstable; that is, they would burn up to form carbon dioxide and water if the system reaches thermodynamic equilibrium. In other words, life processes depend upon the ability to restrict these thermodynamic tendencies by controlled kinetics to produce energy as needed. A key feature of living systems is thus the use of catalysts for the controlled release of that energy. Examples of such catalysts are enzymes that control the synthesis and degradation of biologically important molecules.

Preliminary evidence for enzymes can be attributed to the Swedish chemist Jon Jakob Berzelius, who first assumed in 1835 that the reactions of living organisms were the result of a new power coining the word 'catalysis'. In 1878, the term enzyme, from the Greek *enzymé* meaning 'in yeast' was introduced. In 1890, Emil Fischer intuitively proposed that substrate and enzyme behaved like key in lock illustrating that a substrate had a matching shape to fit into the enzyme active site. Experimentation on enzymes began in 1897, when Eduard Büchner demonstrated enzyme activity in a crude cell-free extract. In 1926, the basis for proving that enzymes are proteins was settled when James B. Sumner crystallized urease from jack bean extracts. Fifteen years later, the first trials to incorporate enzymes to industrial use were attempted and 10 years later the first analytical application of an enzyme was to be described.

Like all catalysts, enzymes increase the rate of chemical reactions without altering the equilibrium constant of the catalyzed reaction and without

## Introduction

Living systems rely on kinetic stability for their existence. They are all thermodynamically unstable; that is, they would burn up to form carbon dioxide and water if the system reaches thermodynamic equilibrium. In other words, life processes depend upon the ability to restrict these thermodynamic tendencies by controlled kinetics to produce energy as needed. A key feature of living systems is thus the use of catalysts for the controlled release of that energy. Examples of such catalysts are enzymes that control the synthesis and degradation of biologically important molecules.

Preliminary evidence for enzymes can be attributed to the Swedish chemist Jon Jakob Berzelius, who first assumed in 1835 that the reactions of living organisms were the result of a new power coining the word 'catalysis'. In 1878, the term enzyme, from the Greek *enzymé* meaning 'in yeast' was introduced. In 1890, Emil Fischer intuitively proposed that substrate and enzyme behaved like key in lock illustrating that a substrate had a matching shape to fit into the enzyme active site. Experimentation on enzymes began in 1897, when Eduard Büchner demonstrated enzyme activity in a crude cell-free extract. In 1926, the basis for proving that enzymes are proteins was settled when James B. Sumner crystallized urease from jack bean extracts. Fifteen years later, the first trials to incorporate enzymes to industrial use were attempted and 10 years later the first analytical application of an enzyme was to be described.

Like all catalysts, enzymes increase the rate of chemical reactions without altering the equilibrium constant of the catalyzed reaction and without

undergoing any net change in their structure. Enzymes are very efficient catalysts, often far superior to conventional chemical catalysts. The relative values over nonenzymatic rates of transformation – acceleration rates – are often  $10^{10}$  as for protease-mediated hydrolysis of peptide bonds, and can reach  $10^{23}$  in the case of orotidine-5'-phosphate decarboxylase (EC 4.1.1.23) in the pyrimidine biosynthetic pathway.

The outstanding characteristic of enzymes over conventional catalysts is their specificity and selectivity. It is this specificity that draws the interest of scientists and technologists for a wide range of applications, from industrial processes to clinical diagnosis or from environmental remediation to drug or food formulation as obvious examples of the key role that enzymes play in our daily life.

Although the fundamentals of enzymes, mainly formulated in the first half of the twentieth century still explain most of the properties of enzymes, multidisciplinary efforts have furnished a realm of new biocatalysts and synthetic enzyme mimics that expand the traditional biocatalytic world toward a new scenario of still nascent technology. The following overview covers all these aspects setting up the fundamentals for the use of enzymes in analytical science.

## Enzyme Structure and General Properties

Enzymes are proteins with the few exceptions of catalytic nucleic acids. Like proteins, enzymes are made up of amino acids linked together by amide bonds. Each peptide chain has one free amino end, the N-terminus, and one free carboxyl end, the C-terminus. The sequence of these amino acids determines the primary structure. Because of the properties of the amino acids, the structure may possess a helical structure ( $\alpha$ -helices) and other possible arrangements such as turns and pleated sheets ( $\beta$ -sheets) resulting in the secondary structure. The tertiary structure of an enzyme refers to its three-dimensional (3D) arrangement in order to minimize nonfavorable thermodynamic interactions with its environment. This 3D structure forms the sites that are directly involved in binding the substrate, the prosthetic group and any other cofactor. The vast majority of known enzymes are composed of two or more polypeptide chains usually linked to each other by noncovalent interactions. These polypeptide chains are termed subunits and may be identical to or different from each other. The combination and spatial arrangement of the subunits is known as the quaternary structure. **Figure 1** shows the 3D

**Figure 1** Three-dimensional view of (A) horseradish peroxidase (HRP 1HCH) and (B) glucose oxidase (GOx 1GAL). HRP from *Armoracia rusticana* is a glycosylated (not shown) monomeric protein with one heme group and two calcium ions. GOx from *Aspergillus niger* is a glycosylated dimeric protein (only one subunit is shown) containing one flavin adenine dinucleotide per monomer. These structures have been obtained from the Protein Data Bank and displayed with the MOLSCRIPT program.

structure of two enzymes of wide application in enzymatic analysis. Many enzymes are glycoproteins containing a large portion of poly- or oligosaccharides derivatives.

For catalytic activity, many enzymes require the presence of a nonprotein component, called a cofactor. The protein part of the enzyme is then termed apoenzyme and the active enzyme, including cofactor, a holoenzyme. Cofactors can range from metal ions, for instance, Zn(II) in alcohol dehydrogenase, to large, complex organic molecules such as nicotinamide adenine dinucleotide (NAD) in some dehydrogenases and flavin adenine dinucleotide (FAD) in some oxidases. The function of the metal ion can be either to provide the catalytic center of the enzyme or it may form a bridging group to link enzyme and substrate together via a coordination complex. If cofactors are tightly bound to apoenzymes, being difficult to remove without damaging the enzyme, they are termed prosthetic groups. The term coenzyme refers to cofactors that are of organic nature. **Figure 2** presents two important cofactors for oxidoreductases.

The catalytic power of enzymes relies on their ability to stabilize the transition state of a reaction relative to that of the ground state ( $\Delta G_{ETS}^{\ddagger} > \Delta G_{ES}^{\ddagger}$ ). This is illustrated in **Figure 3**, also showing that the enzyme–substrate complex is stabilized relative to the free species in solution. Overall, enzymes decrease the Gibbs energy of activation (standard free energy of activation) as compared with non-catalyzed reactions. For instance, the cleavage of hydrogen peroxide normally requires an activation energy of  $75.4 \text{ kJ mol}^{-1}$  and catalase (EC 1.11.1.6) diminishes this energy to  $23 \text{ kJ mol}^{-1}$ .

**Figure 2** Structural formulae of two enzyme cofactors: (A) nicotinamide adenine dinucleotide (NAD) and (B) flavin adenine dinucleotide (FAD) with the corresponding redox transformations in dehydrogenases and oxidases catalyzed reaction, respectively. NAD is a soluble cofactor and it has to be added to the reaction mixture. As shown in **Figure 1**, FAD is bound to the flavoprotein.

Enzymes can exhibit catalytic activity for chemical species that have a given functional group (e.g., phosphate or methyl groups) and have group specificity. If they only act on certain types of chemical bond (e.g., C–C) they show linkage specificity. Stereochemical specificity refers to catalytic activity on reaction of particular stereoisomers or chiral isomers. The stereochemical specificity of enzymes calls for at least three different points of interaction between enzyme and substrate. These interactions can have either a binding or a catalytic function. Binding sites, in the binding domain of the protein, link to specific groups in the substrate, ensuring that the

enzyme and substrate are held together in a fixed orientation with respect to each other. Catalytic sites, in the catalytic domain, link the group or groups of the substrate that are directly involved in the catalysis. The substrate binding site and the catalytic site are usually near one another and frequently overlap. The binding site may be hydrophobic or hydrophilic depending on the complementary structure of substrates; the catalytic site is usually hydrophilic. The region of an enzyme's 3D structure that contains the substrate binding and catalytic site is called the active site or active center. The binding of substrates to enzymes requires the interplay of electrostatic,

**Figure 3** Free energy diagram for catalyzed and uncatalyzed reactions. S, substrate; E, enzyme; P, product; ES, enzyme–substrate complex;  $TS^*$ , transition state;  $\Delta G$ , standard free energy of activation.

hydrogen bonds, and van der Waals interactions. This binding of substrates to enzymes is well explained by the induced fit hypothesis, meaning that upon binding the substrate causes an alteration on the enzyme's conformation resulting in an appropriate orientation for catalysis.

### Heteroenzymes and Isoenzymes

Enzymes exhibiting the same catalytic function are known as homologous enzymes and fall into two classes: heteroenzymes and isoenzymes. The first group includes enzymes derived from different sources but catalyzes identical reaction, yet show different chemical and kinetic characteristics. For instance, the enzyme alcohol dehydrogenase (EC 1.1.1.1), which is found in yeast, is different from the enzyme obtained from horse liver. It is also possible to find this enzyme in several bacteria, plants, and insects. The mammalian enzyme is a dimer with a relative molecular mass of 80 kDa. Two zinc ions are firmly bound to each subunit; one is essential in the catalysis, acting as a Lewis acid. Yeast alcohol dehydrogenase is a tetramer of relative molecular mass of 140–150 kDa, made up of four subunits and containing four active sites. It is generally accepted that there is one zinc ion per subunit. Isoenzymes are different molecular forms of the same enzyme that are found in the same animal or organism, although they show a pattern of distribution between tissues. Lactate dehydrogenase (EC 1.1.1.27) is a classic example of an isoenzyme. In humans, it is composed of two different subunits known as A and B arranged into tetramers and giving five different hybrid forms of the two basic units ( $A_4$ ,  $A_3B$ ,  $A_2B_2$ ,  $AB_3$ , and  $B_4$ ).

They all show different substrate selectivity and inhibition and activation effects, permitting one isoenzyme to function under conditions that would reduce the activity of another. It is likely that such variations aid the control of the same reaction under different cellular or tissue conditions.

### Enzyme Activity and Enzyme Concentration

In principle, the amount of a biocatalyst may be expressed as a number of elementary entities, an amount of substance, a mass, or by a catalytic effect. In many cases, due to the lack of information or for practical reasons, the later route is used. Then, the generally accepted term for the expression of enzyme activity is the Unit (U) defined in terms of reaction rate. One unit (U), accordingly to the International System of Units, is defined as the amount of enzyme that catalyzes the conversion of 1  $\mu\text{mol}$  of substrate (or the formation of 1  $\mu\text{mol}$  of product) in 1 min under standard conditions. The specific activity is the number of units per milligram of protein. If the relative molecular mass of the enzyme is accurately known it is then possible to express the activity as the molar catalytic activity, defined as the number of units per micromole of enzyme. This is, the number of moles of product formed, or substrate consumed, per mole of enzyme per minute. This may not correspond to the number of moles of substrate converted per enzyme active site since the enzyme may contain more than one active site. If the number of active sites per mole is known, then the activity may be expressed correspondingly as the catalytic center activity.

The use of katal (kat) is recommended in the fields of medicine and biochemistry. It differs from the previous units in that the conversion of 1 mol of substrate per second is used ( $1 \text{ kat} = 6 \times 10^7 \text{ Units}$ ;  $1 \text{ U} = 16.67 \text{ nkat}$ ).

### Enzyme Nomenclature

Over 3000 enzymes have so far been identified and this number may be greatly augmented in the wake of genomic and proteomic research. In view of the large number of enzymes and the wide range of catalyzed reactions, it is necessary to have a classification system. Enzymes are generally named for the reaction they catalyze by adding the suffix 'ase'. A systematic scheme of classification was first adopted by the International Union of Biochemistry in 1961 on the basis of the type of catalyzed reaction. Presently, the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology guarantees a strict classification and rational

nomenclature of known and new enzymes. According to this enzyme classification (EC), all enzymes fall into six general groups and they can be identified through four numbers. The first one refers to the main type of reaction. The second and third numbers indicate the subclass and sub-subclasses, respectively, on basis of nature of the actual reaction that is catalyzed. The fourth number is the serial number in its particular subclass. The description of these numbers within the six different classes of enzymes is given in Table 1. For example, the systematic name of lactate dehydrogenase is L-lactate: NAD oxidoreductase with EC number: EC 1.1.1.27. The first number '1' indicates oxido-reductase; the second number '1' of the subclass indicates that it acts on CH–OH groups; the sub-subclass or subgroup is denoted by the third number '1' indicating that NAD is used as H-acceptor; and the last number '27' shows that it is the 27th enzyme in subgroup 1.

The six classes of enzymes are:

**EC1. Oxidoreductases:** to this class belong all enzymes catalyzing oxido-reductions. The substrate oxidized is regarded as hydrogen or electron donor. The classification is based on 'donor:acceptor oxidoreductase'. This class is very important in analytical applications and the most relevant reactions can be summarized as:

**Dehydrogenases.** They catalyze hydrogen transfer from a substrate to an acceptor that is not molecular oxygen; or vice versa. Example: lactate dehydrogenase (EC 1.1.1.27)

**Oxidases.** They catalyze hydrogen transfer from the substrate to molecular oxygen. Example: glucose oxidase (EC 1.1.3.4)

**Peroxidases.** They catalyze the oxidation of a substrate by hydrogen peroxide. Example: horseradish peroxidase (EC 1.11.1.7)

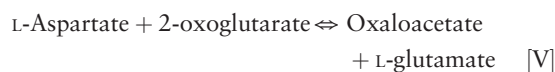

**Oxygenases.** They catalyze substrate oxidation by molecular oxygen with a hydrogen donor that may be the substrate itself. Example: monophenol monooxygenase (EC 1.14.18.1)

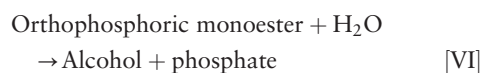

**EC2. Transferases:** enzymes transferring a group, for example, the methyl group or a glycosyl

group, from one compound – generally regarded as the donor – to another compound – generally regarded as the acceptor. The classification is based on the scheme 'donor:acceptor grouptransferase'. Transaminases, transketolases, transaldolases, and transmethyldases belong to this class. Example: aspartate aminotransferase (EC 2.6.1.1)

**EC3. Hydrolases:** these enzymes catalyze the hydrolysis of various bonds. Some of these enzymes pose problems because they have a broad selectivity. According to the type of bond cleaved, a distinction is made between peptidases, esterases, glycosidases, phosphatases, etc. Example: alkaline phosphatase (EC 3.1.3.1)

**EC4. Lyases:** enzymes cleaving C–C, C–O, C–N, and other bonds by other means than by hydrolysis or oxidation. They differ from other enzymes in that two substrates are involved in one reaction direction, but only one in the other direction. Example: mandelonitrile lyase (EC 4.1.2.10)

**EC5. Isomerases:** these enzymes catalyze changes within one molecule. They include racemases, epimerises, mutases, *cis-trans*-isomerases, etc. Example: aldose mutarotase (EC 5.1.3.3)

**EC6. Ligases:** enzymes that catalyze the joining of two molecules with concomitant hydrolysis of the diphosphate bond in ATP or a similar triphosphate. 'Ligase' is commonly used for the common name, but, in a few cases, 'synthase' or 'carboxylase' is used. Example: acetate CoA ligase (EC 6.2.1.1)

## Fundamentals of Enzyme Kinetics

The simplest model of an enzyme-catalyzed reaction is illustrated by:

**Table 1** International classification of enzymes*EC 1. Oxidoreductases: Acting on*

EC 1.1. CH–OH group of donors	EC 1.2. Aldehyde or oxo group of donors	EC 1.3. CH–CH group of donors	EC 1.4. CH–NH <sub>2</sub> group of donors	EC 1.5. CH–NH group of donors
EC 1.6. NADH or NADPH	EC 1.7. Other nitrogenous compounds as donors	EC 1.8. Sulfur group of donors	EC 1.9. Heme group of donors	EC 1.10. Diphenols and related substances as donors
EC 1.11. Peroxide as acceptor	EC 1.12. Hydrogen as donor	EC 1.13. Single donors with incorporation of molecular oxygen (oxygenases)	EC 1.14. Paired donors, with incorporation or reduction of molecular oxygen	EC 1.15. Superoxide radicals as acceptor
EC 1.16. Oxidizing metal ions	EC 1.17. CH <sub>2</sub> groups	EC 1.18. Iron–sulfur proteins as donors	EC 1.19. Reduced flavodoxin as donor	EC 1.20. Phosphorus or arsenic in donors
EC 1.21. X–H and Y–H to form an X–Y bond	EC 1.97. Other oxidoreductases			

*EC 2. Transferases: Transferring*

EC 2.1. One-carbon groups	EC 2.2. Aldehyde or ketonic groups	EC 2.3. Acyl group	EC 2.4. Glycosyl group	EC 2.5. Alkyl or aryl groups, other than methyl groups
EC 2.6. Nitrogenous groups	EC 2.7. Phosphorus-containing groups	EC 2.8. Sulfur-containing groups	EC 2.9. Selenium-containing groups	

*EC 3. Hydrolases: Acting on*

EC 3.1. Ester bonds	EC 3.2. Glycosylases	EC 3.3. Ether bonds	EC 3.4. Peptide bonds (peptidases)	EC 3.5. Carbon–nitrogen bonds, other than peptide bonds
EC 3.6. Acid anhydrides	EC 3.7. Carbon–carbon bonds	EC 3.8. Halide bonds	EC 3.9. Phosphorus–nitrogen bonds	EC 3.10. Sulfur–nitrogen bonds
EC 3.11. Carbon–phosphorus bonds	EC 3.12. Sulfur–sulfur bonds	EC 3.13. Carbon–sulfur bonds		

*EC 4. Lyases*

EC 4.1. Carbon–carbon lyases	EC 4.2. Carbon–oxygen lyases	EC 4.3. Carbon–nitrogen lyases	EC 4.4. Carbon–sulfur lyases	EC 4.5. Carbon–halide lyases
EC 4.99. Other lyases

EC 5.1. Racemases and epimerases	EC 5.2. <i>cis</i> – <i>trans</i> -isomerases	EC 5.3. Intramolecular isomerases	EC 5.4. Intramolecular transferases: mutases	EC 5.5. Intramolecular lyases
EC 5.99. Other isomerases				

*EC 6. Ligases: Forming*

EC 6.1. Carbon–oxygen bonds	EC 6.2. Carbon–sulfur bonds	EC 6.3. Carbon–nitrogen bonds	EC 6.4. Carbon–carbon bonds	EC 6.5. Phosphoric ester bonds
EC 6.6. Nitrogen–metal bonds				

This mechanism consists of two steps; the first one is the binding of enzyme (E) to substrate (S) forming a complex (ES), and the second one includes both the catalysis of the reaction and the release of the

product (P). The formation of an intermediate enzyme–substrate complex has been demonstrated experimentally and is determined by the ratio of two rate constants  $k_1$  and  $k_{-1}$ . These rate constants typically

show values of  $10^5$ – $10^8$   $\text{l mol}^{-1} \text{s}^{-1}$  and  $1$ – $10^4$   $\text{s}^{-1}$ , respectively. For the sake of simplicity, the reverse reaction, determined by  $k_{-2}$ , is not considered in the following treatment. This can be readily assumed at the beginning of the reaction when very little product is formed or when the reaction is not reversible. Thus, the rate of the reaction ( $v$ ) can be calculated as:

$$v = \frac{d[P]}{dt} = k_2[ES] \quad [1]$$

where  $k_2$  is the catalytic rate constant, which is also called  $k_{\text{cat}}$  or turnover number, and it shows typical values of  $1$ – $10^5$   $\text{s}^{-1}$ . The turnover number represents the maximum number of substrate molecules that the enzyme can convert into product per active site and per second.

The evolution of the concentration of the enzyme–substrate complex can be calculated as:

$$\frac{d[ES]}{dt} = k_1[E][S] - (k_{-1} + k_2)[ES] \quad [2]$$

Because the total enzyme concentration  $[E]_t$  equals the free enzyme concentration  $[E]$  and the concentration of the ES complex, eqn [2] can be denoted as:

$$\frac{d[ES]}{dt} = k_1([E]_t - [ES])[S] - (k_{-1} + k_2)[ES] \quad [3]$$

Rearranging terms:

$$\frac{d[ES]}{dt} = k_1[E]_t[S] - (k_1[S] + k_{-1} + k_2)[ES] \quad [4]$$

This gives:

$$\frac{d[ES]/dt}{k_1[S] + k_{-1} + k_2} + [ES] = \frac{k_1[E]_t[S]}{k_1[S] + k_{-1} + k_2} \quad [5]$$

This equation can be greatly simplified in the left-hand side assuming the steady-state approximation by which  $d[ES]/dt$  equals zero. This is, the rate of formation of ES equals its rate of disappearance. However, this is a rather restrictive and unnecessary restriction because eqn [5] can also be simplified when its differential term can be neglected in relation to the concentration of the enzyme–substrate complex:

$$\frac{d[ES]/dt}{k_1[S] + k_{-1} + k_2} \ll [ES] \quad [6]$$

This occurs during a substantial part of the reaction time-course over a wide range of kinetic rate constants and substrate concentrations and at low to moderate enzyme concentrations. An illustration of this assumption is depicted in **Figure 4** where the variation in  $[ES]$ ,  $d[ES]/dt$ ,  $[S]$ , and  $[P]$  with the time-course of the reaction is simulated for a set of values. As seen in the figure, the simplified equation is valid throughout most of the reaction.

**Figure 4** Computer simulation of the progress curves of  $d[ES]/dt$  ( $0$ – $10^{-7}$   $\text{mol l}^{-1}$  scale),  $[S]$  ( $0$ – $10^{-2}$   $\text{mol l}^{-1}$  scale), and  $[P]$  ( $0$ – $10^{-2}$   $\text{mol l}^{-1}$  scale) for a simple Michaelis–Menten kinetics with  $k_1 = 10^6$   $\text{l mol}^{-1} \text{s}^{-1}$ ,  $k_{-1} = 10^3$   $\text{s}^{-1}$ ,  $k_2 = 10$   $\text{s}^{-1}$ ,  $[E] = 10^{-7}$   $\text{mol l}^{-1}$  and  $[S] = 10^{-2}$   $\text{mol l}^{-1}$ . The simulation shows three distinct phases to the reaction time-course, an initial transient phase that lasts for about a millisecond followed by a longer steady-state phase of  $\sim 30$  min when  $[ES]$  remains constant but only a small portion of the substrate reacts. This is followed by the final phase taking  $\sim 6$  h during which the substrate is completely converted to product. (Reproduced with permission from Martin F Chaplin Enzyme Technology.)

The well-known Michaelis–Menten equation is derived from eqns [1] and [5] by introducing the Michaelis constant:

$$K_m = \frac{k_{-1} + k_2}{k_1} \quad [7]$$

Thus, the general reaction rate can be calculated as:

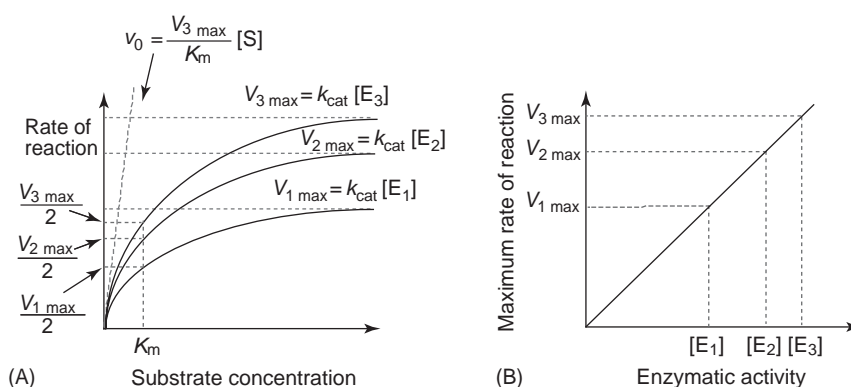

$$v = k_2[ES] = \frac{k_2[E]_t[S]}{[S] + K_m} \quad [8]$$

$k_2[E]_t$  can be considered the maximum rate of reaction ( $V_{\text{max}}$ ) as the maximum value that  $[ES]$  can have is  $[E]_t$  if  $[E]_t < [S]$ . This is, the enzyme is completely saturated with substrate that always occurs when  $[S] \gg K_m$ .

Thus, the reaction rate becomes:

$$v = \frac{V_{\text{max}}[S]}{[S] + K_m} \quad [9]$$

This Michaelis–Menten equation gives the rectangular hyperbolic dependence of the reaction rate on the substrate concentration (**Figure 5A**). This plot represents the actual  $[S]$  over the time-course of the reaction, which only equals the initial substrate concentration at the very beginning of the reaction. Consequently, rate of reactions can only be accurately estimated as initial reaction rates ( $v_0$ ) representing the tangent to the curve at the origin. Also, from this graphical representation, the

**Figure 5** Michaelis–Menten dependence of the reaction rate ( $v$ ) on the substrate concentration  $[S]$ . The hyperbolic relationship is shown in (A) for three different concentrations of enzymes ( $E_1$ ,  $E_2$ , and  $E_3$ ). A typical plot for the determination of the enzyme concentration or activity is shown in (B).

Michaelis constant can be easily interpreted as the concentration of substrate where the rate of the reaction is half of its maximum. This is, at this concentration, half of the enzyme molecules bind the substrate and, thus, it should be independent of the enzyme concentration. However, this is a rather simplistic conclusion because it considers that all enzymes strictly follow the Michaelis–Menten behavior over a wide range of experimental conditions. If not, the  $K_m$  is likely to equal a much more complex relationship between the different rate constants involved. The clear dependence between  $V_{\text{max}}$  and enzyme concentration enables a direct way for the estimation of enzyme concentration (see Figure 5B). This is the case of many clinical determinations targeting key enzymes for diagnostic purposes or the basis of many other assays, e.g., immunoassays, where enzymes are used as reporters or tracers for easy and sensitive transduction of noncatalytic interactions.

It seems clear then that enzymes can be kinetically characterized through  $V_{\text{max}}$  and  $K_m$  values although a more informative value is given by the ratio of both because it includes saturating and nonsaturating conditions of substrate concentration, respectively. For the purpose of comparison,  $k_{\text{cat}}$  instead of  $V_{\text{max}}$  is introduced and then, the ratio  $k_{\text{cat}}/K_m$  determines the relative rate of reaction at low substrate concentration. This ratio is known as the specificity constant since the discrimination between competing substrates is determined by this value that combines both the rate and the binding parameters. The higher the value, the more specific is the enzyme for the particular substrate. Values in the  $10^8$ – $10^9$   $\text{l mol}^{-1} \text{s}^{-1}$  range are claimed to be very close to the maximum rate (kinetic perfection) that could be expected from calculations of the diffusion rates of molecules.

This is to say that enzymes evolve by maximization of this ratio approaching the diffusion-control limit, which is obviously dependent on the equilibrium constant of the catalyzed reaction. Arguably this reasoning is only valid for conditions of initial rates, which are not the typical situation in living cells, where an enzyme is embedded in a chain of reactions with no initial velocities and thus, the driving force of natural selection could be contemplated as reaching the precise  $k_{\text{cat}}/K_m$  value to maximize the conversion of substrate fluxes. Table 2 summarizes the most important parameters that define the kinetics of a monomolecular enzyme-catalyzed reaction.

Similarly to complex enzymatic pathways in living systems, coupled enzyme reactions are very often used for analytical purposes. In a simplified case:

where  $S_1$  and  $P$  denote the analyte and the transducing compounds, respectively. In this case the intermediate reactions should not limit the overall reaction and thus:

$$\frac{k_{\text{cat}}}{K_m} (E_1) \leq \frac{k_{\text{cat}}}{K_m} (E_2) \leq \frac{k_{\text{cat}}}{K_m} (E_3) \quad [11]$$

The kinetics of reversible reactions demands a more laborious mathematical treatment. The reader can find a detailed description in the recommended reading. It should be stressed that enzymes can favor a reaction in one direction rather than its reverse. This is not contradictory with the fact that enzymes can never alter the equilibrium constant of a catalyzed reaction because they can favor one direction by binding strongly, as enzyme–reactants complexes, the

**Table 2** Kinetic terms used in enzyme catalyzed reactions:  $E + S \xrightleftharpoons[k_{-1}]{k_1} ES \xrightleftharpoons[k_{-2}]{k_2} E + P$ 

Definition	Symbols	Mathematical expression	Units
Maximum rate of reaction	$V_{\max}$	$k_2[E]_t$	$\text{mol l}^{-1} \text{s}^{-1}$
Rate of reaction	$v$	$V_{\max}[S]/([S] + K_m)$	$\text{mol l}^{-1} \text{s}^{-1}$
Initial rate of reaction	$v_0$	$V_{\max}[S]/K_m$	$\text{mol l}^{-1} \text{s}^{-1}$
Michaelis constant	$K_m$	$k_{-1} + k_2/k_1$	$\text{mol l}^{-1}$
Catalytic rate constant or turnover number	$k_2(k_{\text{cat}})$	$V_{\max}/[E]_t$	$\text{s}^{-1}$
Specificity constant	$k_{\text{cat}}/K_m$		$\text{l mol}^{-1} \text{s}^{-1}$
Acceleration rate	$k_{\text{cat}}/k_{\text{uncat}}$		
Equilibrium constant of the reaction	$K$	$k_1 k_2/k_{-1}$	

reactants in the preferred direction whilst binding weakly the products. Consequently, it is unlikely that the same enzyme would be optimum for catalyzing a reversible reaction in both directions.

The knowledge of these kinetic constants is then of high importance in order to choose the right enzyme and the right conditions for an analytical application. Either endpoint or kinetic methods can be applied. If a nearly complete conversion of substrate in a reasonable time is pursued, then the  $K_m$  of the enzyme should be as small as possible. This is of special importance to maintain a relatively high rate of reaction for the determination of analytes at low concentration ( $[S] < K_m$ ). Because the reaction rate is directly proportional to the amount of enzyme (eqn [9]), a high concentration of enzyme, represented by  $V_{\max}$ , is desirable to shorten the time of analysis or response time:

$$t = \frac{X[S]}{V_{\max}} - \frac{K_m \ln(1 - X)}{V_{\max}} \quad [12]$$

where X denotes the fractional conversion  $[S] - [P]/[S]$ .

Alternatively, if the equilibrium constant is not favorable or the  $K_m$  is too high in relation to the target concentrations ( $[S] \ll K_m$ ), then a kinetic method can be applied. Equation [9] can then be simplified to:

$$v = \frac{V_{\max}[S]}{K_m} \quad [13]$$

In general, to maintain a direct proportionality between the rate of reaction and the concentration of analyte, this should be much smaller than the  $K_m$  ( $[S] < K_m$ ). The specificity constant and the amount of enzyme will then determine the sensitivity of the assay whilst its dynamic range will be limited by the value of  $K_m$ .

For the estimation of  $K_m$  and  $V_{\max}$ , different graphical plots can be obtained after measurement of the reaction rates over a wide range of substrate concentration. These methods are illustrated in Figure 6. The Lineweaver–Burk plot or double reciprocal

( $1/v$  versus  $1/S$ ), or the Eadie–Hofstee plot ( $v$  versus  $v/S$ ) should never be used to calculate  $K_m$  and  $V_{\max}$  values for publication. The Lineweaver–Burk plot is preferred to test for the qualitative correctness of the enzyme mechanism and the Eadie–Hofstee plot is preferred for discovering deviations from linearity. The Hanes plot ( $S/v$  versus  $S$ ) is less dangerous but, even so, for statistical reasons these three plots should not be used for anything other than display purposes. There is only one statistically sound method for the determination of the best fit  $K_m$  and  $V_{\max}$  values by visual inspection of a graph. This is the direct linear plot that uses a nonparametric criterion of best fit, in which the median values of a series of estimates of  $K_m$  and  $V_{\max}$  are shown to be the best. This method depends upon the assumption that any errors in the experimental data are as likely to be positive (too high) as negative (too low). The usual objection to any graphical method of calculating these values is that confidence limits or standard deviations are not determined whilst the direct linear plot does not suffer from this disadvantage.

### Allosteric Enzymes

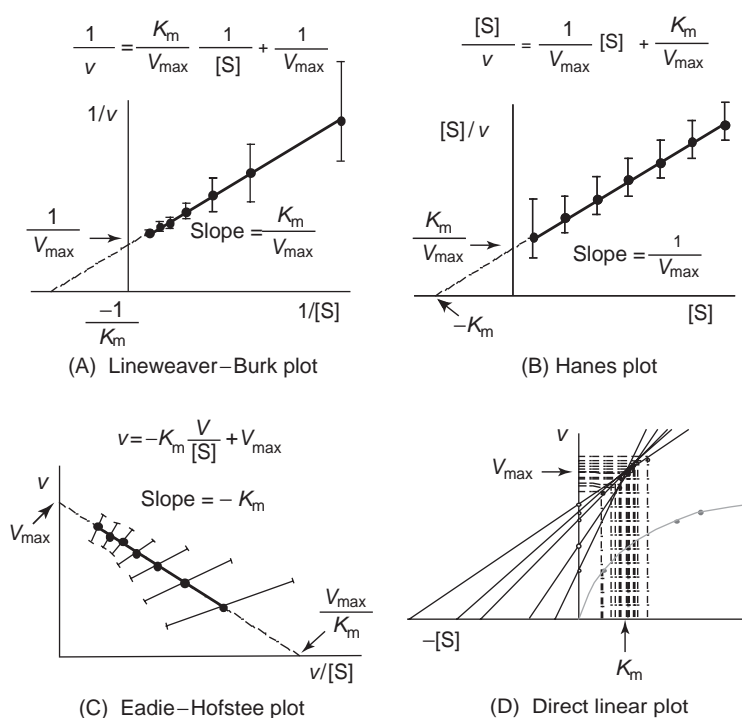

A large family of enzymes that deviate from hyperbolic kinetics (Michaelis) is the allosteric enzymes. These enzymes contain two or more topologically distinct binding sites that interact functionally with each other. Most commonly, sigmoidal or S-shaped curves are obtained, being indicative of positive substrate cooperativity. The reaction rate for these enzymes can be calculated by the Hill equation:

$$v = \frac{V_{\max}[S]^b}{K^b + [S]^b} \quad [14]$$

Rearrangement of this equation to a linear form gives:

$$\log \frac{v}{V_{\max} - v} = b \log [S] - \log K \quad [15]$$

**Figure 6** Different graphical representations of the estimated reaction rates at different concentrations of substrate. The different plots show the relative weight of standard deviations at the given concentrations assayed.

$K$  and  $h$  represent a kind of Michaelis constant and the Hill coefficient, respectively. If  $V_{\max}$  is known, these constants can be calculated from the slope and intercept of the Hill plot (eqn [15]). If the Hill coefficient results equal to one, then there is no cooperativity and the graph is hyperbolic. An increasing value of  $h$  will show an increasingly sigmoidal curve with positive cooperativity for the substrate. A value less than one shows negative cooperativity. The reaction rate of these enzymes is easily controlled by allosteric effectors, activators, or inhibitors, this mechanism being of crucial importance for the control of metabolic pathways. Equally important, this mechanism can also be used for the detection of analytes.

## Kinetic Mechanisms of Multisubstrate Systems

Many enzyme-catalyzed reactions involve two or more substrates and enzyme complexes and hence they deviate from the Michaelis-Menten treatment. A direct simplification of this situation consists of keeping one substrate at nonlimiting concentration. For instance, reactions with  $\text{NAD}^+/\text{NADH}$  dependent dehydrogenases or oxidases using molecular oxygen as electron donor can be readily

simplified to single substrate kinetics by using a saturating concentration of the soluble cofactor or dissolved oxygen, respectively (pseudo-first-order conditions).

Kinetic mechanisms of multisubstrate reactions can be broadly divided into two main types, sequential and ping-pong (also known as double displacement). These mechanisms can be easily illustrated by Cleland plots where the enzyme is represented as a horizontal line and arrows denote the addition of substrates and release of products (Figure 7). In sequential reactions, all substrates bind to the enzyme before the first product is released. They can be further subdivided into ordered and random reactions. The ordered sequential mechanism imposes that the binding of substrates to the enzyme and the release of products follow a defined sequence. In contrast, the random sequential mechanism does not demand any specified order and alternate reaction sequences exist. The distinguishing feature of enzymes under a ping-pong mechanism is that at least one product is released from the enzyme before all of substrates have bound and the enzyme will exist in two or more stable forms between which it oscillates during the reaction.

These mechanisms can be distinguished by keeping one substrate (e.g., A in Figure 7) at a constant concentration (fixed concentration) and varying the concentration of the other substrate. Then, if increased

**Figure 7** Cleland plots of the different mechanisms in multisubstrate enzyme-catalyzed reactions: (A) sequential mechanism, ordered (left) and random (right); (B) ping-pong mechanism. The double reciprocal plots identify either mechanism. Ordered and random show identical data display. 1, 2, 3, ..., 5 denote increasing concentrations of the second substrate.

concentrations of the fixed substrate are assayed and data obtained are represented as Lineweaver–Burk plots, the different pattern of lines is indicative of the enzyme mechanism.

## Factors Affecting Enzyme Activity

Most enzymes are adapted to function in a rather limited set of physiological conditions: chemical and ionic composition of the medium, pH, temperature, pressure, or other chemical species.

### Temperature

Like all reaction rates, temperature increases the reaction rate according to the Arrhenius equation:

$$k = Ae^{-E_a/RT} \quad [16]$$

where  $k$  is the kinetic rate constant,  $A$  the Arrhenius constant,  $E_a$  the standard free energy of activation,  $R$  the gas constant, and  $T$  the absolute temperature. From eqn [16], the energy of activation of the enzyme-catalyzed reaction can be directly calculated:

$$\ln k = \ln A - \frac{E_a}{R} \frac{1}{T} \quad [17]$$

The increase of rate constant with temperature is limited by the inherent thermal instability of enzymes that can be categorized into two types. The first one

is time dependent and consists of gradual and irreversible loss of enzymatic activity on exposure to high temperatures. The second is heat-induced, cooperative unfolding of enzyme molecules, usually almost instantaneous and reversible (melting temperature). Time-dependent thermal inactivation is a rather complex process that may be simplified by one-stage first-order kinetics, which proposes the transition of a fully active native enzyme to a fully inactivated species in a single step. This mechanism leads to a model of exponential decay enabling the calculation of the half-life:

$$t_{1/2} = \frac{0.693}{k_d} \quad [18]$$

where  $k_d$  is the rate constant of enzyme inactivation. The half-life ( $t_{1/2}$ ) of an enzyme is the time it takes for the activity to reduce to half of the original activity. Although temperature may not be the only inactivating factor for an enzyme, a clear distinction should be made between operational and shelf-life (storage) stability. Both should be determined under  $V_{\max}$  conditions but the first one clearly denotes the time for an enzyme to decay in its activity under continuous operation. In order to minimize loss of activity on storage, dry conditions, concentrated enzyme solutions, or addition of additives preventing freezing (e.g., glycerol) extend the shelf-life of enzymes for extended periods of time.

## pH and Ionic Strength

Enzymes are very sensitive to pH because they are amphoteric molecules. Typically and unless other factors are taken into account, they show a rate of reaction with respect to pH that follows a bell-shaped curve. At the pH optimum, the conformation of the enzyme at that particular environment, the pattern of charges in the active site, and the ionization of substrates, products, and enzyme–substrate complex enzymes (if charged molecules) are most favorable for a maximum rate. In choosing a buffer for an analytical application, zwitterionic buffers are more suitable because they do not bind appreciably to divalent ions, very often essential for catalysis, and are chemically stable. In addition to pH, the ionic strength of the medium may substantially alter the rate of the reaction. High ionic strength will diminish water activity in addition to detrimental effects on the binding of charged substrates to enzymes and on the movement of charged groups within the active site. Thus, it is best to use buffers at the lowest concentration necessary to give adequate buffering capacity for the enzyme-catalyzed reaction.

## Other Chemical Species

Enzyme-catalyzed reactions can be strongly inhibited by the presence of other compounds. This effect sets the basis for many enzyme assays enabling, in the presence of a substrate, the determination of the concentration of the inhibitor (analyte). There are two mechanisms of inhibition: reversible and irreversible. Reversible inhibition can be further distinguished as: competitive, noncompetitive, uncompetitive, and mixed type of inhibition. A brief scheme of the most important mechanisms is depicted in Figure 8.

**Figure 8** Scheme of different enzyme inhibition mechanisms, where  $k_i$  and  $I$  denote the inhibition constant and the inhibitor, respectively.

## Traditional Enzymes in New Environments and New Enzymes in Traditional Environments

Enzymes have had billions of years to evolve as needed in living systems but none of these needs are spontaneously driven by technological or analytical challenges. Thus, the most obvious disadvantage in exploiting the exquisite specificity and rate of accelerations of enzymes is their inherent instability in addition to a rather narrow set of conditions for optimal activity. Much effort is being invested in search of: (1) different performance of classical enzymes, (2) new biocatalysts, and (3) synthetic molecules exhibiting the essence of the biocatalytic activity.

## Enzymes in Nonaqueous Solvents

Over the past 15 years, it has been firmly established that many enzymes can work in organic solvents containing little or no water. In general, hydrophobic solvents are preferred to hydrophilic ones because the latter have a greater tendency to strip tightly bound water – essential for catalytic activity – from the enzyme molecule. Although much of the interest for enzymes in organic media is driven by synthetic purposes, challenging analytical applications could be easily implemented. Examples include: online coupling of sample pretreatment and biocatalytic detection, pre- or postcolumn biocatalytic transformations within chromatographic separation, or direct biocatalytic detection of nonsoluble analytes.

In general, reaction rates of enzymes are far lower in neat organic solvents than in water. Enzyme structural changes and conformational mobility, pH constraints, and the energetics of substrate desolvation and transition state destabilization are claimed to be the major reasons for lowering the enzyme activity in organic media. These factors contribute very differently to the catalytic activity and may not be strictly ascribed to the effect of the organic media or are very dependent on the polarity of the solvent. For instance, structural changes of enzymes are rather related to the prior enzyme dehydration during lyophilization than to the direct contact with an organic solvent. Contrarily, organic solvents reduce the conformational mobility of enzymes due to the lack of multiple hydrogen bonds with the solvent and to stronger electrostatic intramolecular interactions and, thus, resulting in a much more rigid enzyme conformation with decreased catalytic activity. In fact, enzymes can only exhibit catalytic activity in organic media because they can retain some essential water in anhydrous solvents. Substrate desolvation from the reaction media to the active site is the first

step for the formation of the enzyme–substrate complex. The more energetically favorable this desolvation is, the greater the net binding energy becomes ( $\Delta G_{ES}$ , see **Figure 3**). Many enzymes have hydrophobic active centers and work best with hydrophobic substrates because they tend to partition more favorably from aqueous media into the active center. Replacement of water with an organic solvent stabilizes the ground state of hydrophobic substrate and hence slowing down the reaction rate. The energy of the transition state in organic solvents can also contribute to this detrimental reaction rate, particularly if the transition state is highly polar and is exposed to the solvent. Water will then tend to stabilize it much better than less polar solvents also resulting in lower activity in nonaqueous media. In contrast to biocatalysis in aqueous solution, the influence of pH in organic media is meaningless. Enzymes have shown a pH memory effect meaning that their catalytic behavior in organic media reflects the pH of the last aqueous solution to which they were exposed.

All these considerations should be contemplated in light of the intriguing properties that enzymes can show in nonaqueous media. For instance, enzymes are insoluble in almost all organic media providing thus a direct and simple way of immobilization. Similarly to immobilized systems, diffusional limitations may account for lower catalytic activity compared with that in homogeneous systems. The two types of thermal instabilities can be suppressed to a certain extent by organic media. In fact, thermal unfolding of some enzymes may require higher temperatures in anhydrous media than in water and, likewise, the half-lives of enzymes at high temperatures can be significantly extended. In this regard, the conformational rigidity of enzymes in anhydrous media turns now to be of great advantage. Of particular importance is the fact that classical organic reactions traditionally prohibited to biocatalytic pathways can now be easily performed and, equally important, the enzymatic selectivity can be changed dramatically on switching from one solvent to another.

### Extremozymes

Most of the enzymes used to date are obtained from mesophilic organisms and, thus, their limited stability to temperature, pH, or ionic strength. Extremophiles are organisms that have evolved to exist in a variety of extreme environments. **Table 3** lists the range of habitats where extremophiles have been found and some of the identified extremozymes. Adaptation to extreme conditions means that these enzymes have the same order of magnitude of activity and stability but at different temperatures, ionic

strengths, etc. Different factors contribute to the adaptation of extremozymes. Among them: changes in specific amino acid residues, increased number of ion pairs, reduced ratio of surface area to volume, reduction in the size of loops and in the number of cavities, increased hydrophobic interaction at subunit interfaces, changes in solvent-exposed surface areas, increase in the extent of secondary structure formation, and truncated amino and carboxyl termini.

Development of the polymerase chain reaction has been to a large extent facilitated by the availability of thermostable DNA polymerases, enzymes that catalyze the elongation of the primer DNA strand. So far, this is the largest application of thermophilic enzymes.

### Protein Engineering

By the use of genetic or/and chemical techniques, the structure and function of an enzyme can be deliberately altered resulting in new properties. In contrast to molecular biology tools, chemical modification of enzymes enables an almost unlimited introduction of chemical groups, but the reactions used for this purpose are typically nonspecific. Thus, nonspecific modifications of multiple sites create mixtures of enzymes as a result of poorly discriminating or insufficiently efficient chemistry. An example of successful chemical modification of cationic horseradish peroxidase is illustrated in **Figure 9**. By chemical binding of sulfonate derivatives to the glycosidic residues of the enzyme, its pI is shifted to yield an anionic peroxidase that shows strong electrostatic interaction with positively charged redox mediators for electrochemical communication.

Genetic modification falls into two categories: random mutagenesis and site-directed mutagenesis. The first one constitutes the basis of directed evolution (see below) whilst the second one changes – in a rational manner – a specific amino acid into another by changing the gene sequence for the protein. Thus, the technique is basically limited to the 20 amino acids – encoded by the Genetic Code – at each position of the peptide chain and it requires a precise knowledge of the relationship between sequence, structure, and mechanism. A large variety of DNA technology is nowadays available producing engineered enzymes that deeply contribute to the understanding of enzyme mechanisms.

### Directed Evolution of Enzymes

This technique mimics in the laboratory the natural evolution processes of enzymes, including random mutagenesis and recombination for engineering enzymes in search of specific capabilities, especially

**Table 3** Different kinds of enzymes found in extreme conditions

Phenotype	Habitat	Enzymes	Typical genera
Thermophilic	High temperatures: Moderate thermophiles (45–65°C) Thermophiles (65–85°C) Hyperthermophiles (> 85°C)	Amylases, xylanases, proteases, DNA polymerases	<i>Methanobacterium</i> , <i>Thermoplasma</i> , <i>Thermus</i> <sup>a</sup> , some <i>Bacillus</i> <sup>a</sup> species, <i>Aquifex</i> <sup>a</sup> , <i>Archaeoglobus</i> , <i>Hydrogenobacter</i> <sup>a</sup> , <i>Methanothermus</i> , <i>Pyrococcus</i> , <i>Pyrodictium</i> , <i>Pyrolobus</i> , <i>Sulfolobus</i> , <i>Thermococcus</i> , <i>Thermoproteus</i> , <i>Thermotoga</i> <sup>a</sup>
Psychrophilic	– 2 to 20°C	Proteases, dehydrogenases, amylases	<i>Alteromonas</i> <sup>a</sup> , <i>Psychrobacter</i> <sup>a</sup>
Acidophilic	pH < 4	Sulfur oxidation, chalcopryrite concentrate	<i>Acidianus</i> , <i>Desulfurolobus</i> , <i>Sulfolobus</i> , <i>Thiobacillus</i> <sup>a</sup>
Alkalophilic	pH > 9	Cellulases	<i>Natronobacterium</i> , <i>Natronococcus</i> , some <i>Bacillus</i> <sup>a</sup> species
Halophilic	2–5 mol l <sup>–1</sup> NaCl	Malate dehydrogenase, <i>p</i> -nitrophenylphosphate phosphatase	<i>Haloarcula</i> , <i>Halobacterium</i> , <i>Haloferax</i> , <i>Halorubrum</i>
Piezophilic	High pressure	Whole microorganism	
Metalophilic	High metal concentration	Whole microorganism	
Radiophilic	High radiation levels	Whole microorganism	

<sup>a</sup>Genera of the domain Bacteria; all others are Archaea.

increased catalytic activity, enhanced selectivity, or improved stability. Similarly to the process by which Nature has produced enzymes without using any knowledge of structure and function, direct

evolution of enzymes generates a library of proteins. The two key steps are the generation of molecular diversity and the identification of the variants that possess specific characteristics. This is schematically illustrated in **Figure 10**. After the generation of the library of mutant genes using molecular biology methods (e.g., error-prone polymerase chain reaction), they are inserted in an appropriate microorganism. Mutant enzymes (variants) are then expressed, after being individually screened for the specific property. The mutant gene of the optimal enzyme variant is then subjected once more to the process: mutagenesis/expression/screening. This creates a pressure leading to the formation and identification of an ever better enzyme. The high throughput screen of enzyme variants is challenging and detrimental for successful process because the frequency of improved mutants might be 1 in 1000. Given that the most common enzymatic assays are not sensitive enough for single-cell analysis, screening of populations comprised of colonies is predominantly used. This technique can be viewed in parallel with the emergence of combinatorial methods in organic synthesis for lead identification and optimization of new drugs or synthetic enzymes (see below).

### Catalytic Antibodies

In common with enzymes, antibodies can specifically bind a large range of chemical structures and using the same type of molecular interactions, but, in

**Figure 10** Key steps of a typical directed enzyme evolution experiment.

contrast, the immunoglobulins bind tightly to the target molecule in their ground state and then are unable to catalyze reactions. Hence, by producing an antibody specific for the transition state, the same catalytic effect should be observed. This is the basic idea, already formulated in 1969 by Bill Jencks, behind catalytic antibodies (abzymes) that can be produced through classical immunization procedures or can also be isolated from sera of patients with several diseases. As the transition state is by definition unstable, it is necessary to use an analog of this structure to raise the abzymes. In general, catalytic antibodies display a high degree of stereospecificity although their rates of accelerations ( $10^3$ – $10^4$ ) are much smaller when compared to their enzymatic counterparts. In principle, catalytic antibodies represent a promising field for analytical applications if the vast repertoire of antibodies produced by the immune system and the possibilities of DNA technology for their production is balanced versus the number of reactions catalyzed by enzymes. So far, more than 100 reactions have been accelerated by antibodies, including reactions for which no enzyme exists.

### Nonprotein Enzymes: Catalytic RNA

Since 1982, it is recognized that nucleic acids and particularly RNA may catalyze a broad range of reactions such as formation, cleavage, and rearrangements of some chemical bonds. Catalytic RNAs are known as ribozymes and they can be found in organelles of plants and lower eukaryotes, in amphibians, in prokaryotes, in bacteriophages, and in viroids or satellite viruses. Arguably they may not

be considered true biocatalysts since they suffer a net change in the catalyzed reaction. The exception is the RNase P, which is an endoribonuclease responsible of the removal of 5' leader sequences from transfer RNA precursors. In bacteria, this RNase P consists of two subunits, a large ( $\approx 140$  kDa, 400 nucleotides) RNA and a small ( $\approx 14$  kDa, 120-amino acids) protein. *In vivo*, both subunits are strictly necessary to exhibit catalytic activity whilst *in vitro* the RNA subunit is itself catalytically active at high ionic strength and in the absence of the protein.

The use of engineered nucleic acids has allowed to convert most of the ribozymes in true biocatalyst resulting in specificity constants ( $k_{\text{cat}}/K_m$ ) up to  $10^8 \text{ l mol}^{-1} \text{ min}^{-1}$  although the acceleration rate still remains  $\sim 10^3$ -fold lower than those provided by protein enzymes catalyzing comparable reactions. All known ribozymes require a doubly charged cation, usually  $\text{Mg}^{2+}$ , which is required, in some cases, for proper assembly of a complex 3D structure.

*In vitro* selection methods permit the generation of ribozymes and deoxyribozymes (catalytic DNA) with allosteric properties, wherein the binding of an effector molecule controls the catalytic function. This feature provides challenging opportunities for the development of new analytical and very specific tools using traditional assay formats or for the development of entirely new biosensing principles.

### Synthetic Enzymes

Presently, there is great effort to produce synthetic equivalents to enzymes that being inherently stable could rival rate of accelerations and specificity. Basically, there are three different synthetic routes to mimic enzymes: (1) the design approach, (2) the transition state analog (TSA)-selection approach, and (3) the catalytic activity-selection approach. In the first one, a host molecule is modified with a functionality that being present in the natural counterpart is expected to render catalytic properties (e.g., catalytic cyclodextrins). This may demand a substantial synthetic effort for a given enzyme mimic. In contrast, the TSA-selection approach relies on the generation of a library of hosts in the presence of TSA and the best host is then selected recalling the natural abzymes generation. Catalytic molecularly imprinted polymers (MIPs) are a much younger field than its biological counterpart but the basic concepts remain very similar. Molecular imprinting is a polymerization process resulting in porous polymers with binding sites that can selectively bind the molecule with which they were imprinted. If the imprint

molecule is a TSA, the resulting MIP should then show catalytic properties. The present scope of catalytic MIPs is still relatively limited. These two methods face the common failure that the desired property of catalysis is not in the screening criteria. In contrast, the catalytic activity-selection approach takes advantage of the combinatorial chemistry revolution wherein a library of possible catalysts is generated and screened directly for enzyme-like activity.

## Introduction

Enzymes are exploited as catalysts in many industrial, biomedical, and analytical processes. There has been considerable interest in the development of carrier systems for enzyme immobilization because immobilized enzymes have enhanced stability compared to soluble enzymes, and can easily be separated from the reaction. This leads to significant savings in terms of reduced enzyme consumption, and the ability to use such enzymes in continuous processes. The activity and stability of enzymes depends largely on the particular operating and storage conditions, and is strongly influenced by factors such as the chemical environment, temperature, pH, and solvent properties. Most enzymes are water soluble and a certain amount of water is always required for their solubilization. Additionally, many enzymes require the presence of a cofactor, which may be attached firmly to the enzyme or may need to be added separately as a coenzyme. When the immobilization of an enzyme

is considered, the above factors need to be taken into consideration.

Immobilized enzymes are defined as biocatalysts that are restrained or localized in a microenvironment yet retain their catalytic properties. Immobilization often increases stability and makes the reuse of the enzyme preparation very simple. The repeated analysis that can be performed by the use of enzymes in an immobilized form reduces the cost of the analysis. The ideal immobilization procedure for a given enzyme is one which permits a high turnover rate of the enzyme yet also retains a high catalytic activity over time. There are two major applications for immobilized enzymes in analytical systems. In one, the enzyme is immobilized onto a particulate solid support matrix, which is then packed into a small column and incorporated into a flow system. The other involves immobilization within or on the surface of an electrode, whereby the electrochemical transduction of enzymatic product is monitored.

Many experiments have shown that the advantages of immobilized enzymes extend beyond their reusability. Their physicochemical properties are often significantly modified compared to those of the corresponding enzyme in free solution. The immobilized enzyme usually has a lower activity than the same mass of enzyme in solution. Nevertheless,

unless the activity losses are severe this disadvantage is not serious, and can be compensated by using more of the immobilized preparation, knowing that it can be used repeatedly.

A significant advantage of immobilization is the increased thermal stability conferred on many enzymes, allowing their use for longer periods at higher temperatures than would be possible for the soluble molecule. An early experiment showed that immobilized papain (a protease derived from papaya latex) retained over half its room-temperature activity at 80°C in conditions under which the soluble enzyme was almost entirely denatured.

Also interesting and valuable are the changes in the pH-activity curves that often accompany immobilization. A common result is broadening of the curve, i.e., the enzyme is active over a wider pH range than its soluble counterpart. This is normally attributed to the range of microenvironments of different enzyme molecules in or on the solid matrix. Depending on the charge properties of this matrix, the optimum pH may undergo significant shifts. The optimum pH for an enzyme bound to a negatively charged carrier such as carboxymethylcellulose is shifted to higher values, while immobilization on a cationic matrix such as diethylaminoethyl-cellulose (DEAE-cellulose) has the opposite effect. These effects may reflect the change in the enzyme's microenvironment brought about by neighboring charged groups. Immobilization on a neutral carrier would not be expected to change the pH optimum.

Despite the advantages of enzymes immobilized on noncatalytic matrices, the yield and productivity of the reaction can be reduced simply due to the presence of the noncatalytic mass of the carrier. There has therefore been much interest in the development of carrier-free systems, in which enzyme molecules are linked to each other to form large complexes. These are inherently immobilized because individual enzyme molecules are no longer free to diffuse in solution, but they are largely undiluted by inert molecules and therefore retain a greater degree of activity than carrier-bound enzymes. This article discusses strategies for enzyme immobilization in carrier-based and carrier-free systems and considers some of their major applications.

## Immobilized Enzyme Reactors

Enzymes may be immobilized onto a number of different types of matrix, including beads, fibers, films, membranes, and even enclosed capsules (Figure 1A). The means of association may be covalent or non-covalent. There is no general rule as to the optimum

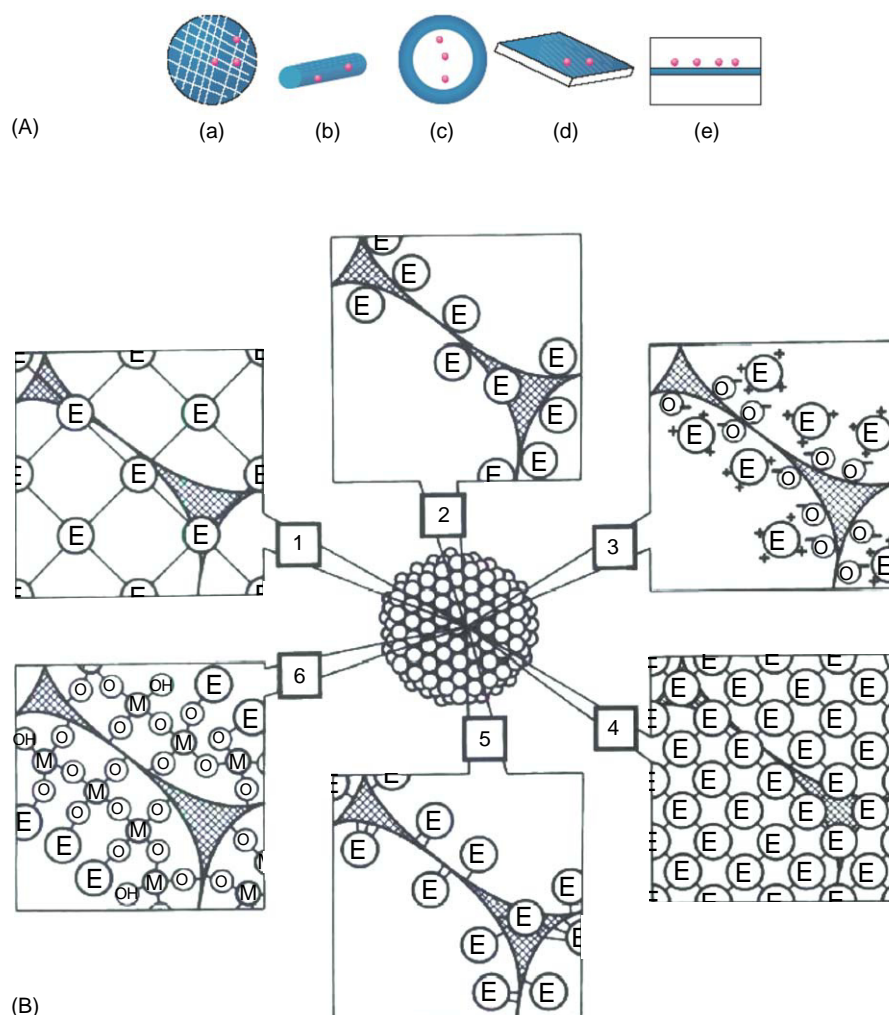

immobilization procedure and an empirical approach is always required. Various alternative coupling reactions have been used, the most common of which are adsorption, covalent binding, electrostatic binding, intermolecular cross-linking, gel entrapment, and chelation (Figure 1B).

Immobilization of enzymes by means of covalent coupling to a reactive insoluble support or to the surface of an electrode is the method of choice if a long operational performance is required. The covalent binding should involve functional groups on the enzyme that are not required for catalytic activity and do not lie near the active site. In general, binding is achieved by a nucleophilic group on the enzyme reacting with an activated functional group on the support material. Amino, hydroxyl, and thiol groups on the enzyme may participate in the linkage. Cysteine, lysine, tyrosine, and histidine residues are most commonly involved in such coupling reactions.

The matrices most widely used for enzyme immobilization are made from controlled-pore glass. This is a macroporous, high-silica glass commonly used in both flow injection and liquid chromatography systems. The support comprises particles or beads (typically ~10 µm diameter) with bonded functionalities, such as C<sub>18</sub> (octadecyl), alkylamino-bonded (–NH<sub>2</sub>), or zirconium-treated silica matrices. Polymeric supports are also commonly used as carriers. Some typical polymers include vinylsulfone-hydroxymethyl methacrylate, poly(vinylalcohol) beads, polyacrylamide gels, 2-fluoro-1-methylpyridinium salt-activated Fractogel, hexamethylacrylate polymer (Sepharon Herma E, an anion exchange polymer), chlormethylated polystyrene beads, and beaded cellulose. Polysaccharide stationary phases like agarose have also been used as enzyme supports, e.g., cyanogen bromide-activated Sepharose 4B.

Some of these enzyme supports are available from the manufacturers as dry or ready-to-use preparations or can be purchased in the form of prepacked columns. Generally, these phases are already activated and immobilization is achieved by recirculating the enzyme solution for a given time at a pH appropriate for the binding reaction. The activation and immobilization conditions are generally provided by the suppliers.

Matrix functionalities that are often used in covalent binding reactions for enzyme immobilization include aminoalkyl, arylamine, 3-glycidopropyl, carboxyl, 3-mercaptopropyl and alkylhalide groups. The most commonly used immobilization techniques are illustrated in Figure 2. Alkylamine- and arylamine-functionalized supports are shown with glutaraldehyde and azo coupling, respectively. For silica or glass supports, the functionalities are

**Figure 1** (A) Carrier-bound immobilized enzymes of defined size and shape. Insoluble carriers vary in their geometric parameters. Different shapes and types of enzyme carrier are illustrated: (a) bead, (b) fiber, (c) capsule, (d) film, and (e) membrane. (B) Methods used for immobilizing enzymes onto a spherical solid support matrix: 1, physical absorption; 2, covalent binding; 3, electrostatic binding; 4, intermolecular cross-linking; 5, gel entrapment; 6, chelation and/or metal binding. E, enzyme; M, metal.

usually obtained through silanization of the support with a silane derivative. The best known covalent linkage methods include the use of cyanogen bromide (CNBr) or chloro-*sym*-triazinyl groups to bind  $\text{-NH}_2$  groups to hydroxylic matrices such as agarose or cellulose, and the use of carbodiimides to link amine and carboxylic acid functional groups between enzymes and solid phases. Such covalent linkages are not infinitely stable, and even the best immobilized enzyme reactors run down after several months through slow leakage of the enzyme into solution.

Controlled-pore glass with aminopropyl functional groups has proven to be the most successful support for enzyme immobilization. Most enzymes immobilized on this support, e.g., with glutaraldehyde, retain their activities. The goal is to achieve maximal loading of the active enzyme, resulting in optimal

conversion efficiency per unit volume of the non-catalytic matrix.

Activation of the functionalized support is most often achieved with glutaraldehyde, which introduces a carbonyl residue that subsequently reacts with nucleophilic groups on the enzyme. The activation of the functional material and the binding of the enzyme result in the formation of a Schiff base. The optimum pH for these reactions is a compromise between the preferred acidic catalytic conditions, the  $\text{pK}_a$  of the nucleophilic groups (in such a way that the unprotonated form is desirable) and the stability of the enzyme at different pH values. The reversibility of Schiff base formation is suppressed by the addition of sodium cyanotrihydroborate, a weak reducing agent, which does not reduce aldehydes or ketones at neutral pH but readily reduces the imine form to the

**Figure 2** Schemes of the most commonly used immobilization techniques. amine form. Another important aspect of the addition of cyanotrihydroborate is that the imine product itself is a reactive species and is prone to further reaction, resulting in the addition of new nucleophilic agents to the imine bond. If water is the nucleophile, the transimination reaction may result in unsuccessful activation of the functionalized material.

There is also a trend toward the utilization of polymer-based supports. These are known to be more stable under alkaline conditions, resulting in reduced band broadening effects compared with silica and glass phases. These effects are most clearly seen in flow systems (flow injection and liquid chromatography) in the determination of solutes that are catalyzed at a higher pH.

Successful enzyme immobilization depends on the structure of the porous support. Small pores provide a large total surface area because of their larger internal surface, while larger pores provide a smaller surface area. The efficiency of the immobilized enzyme can be improved by chromatographic purification of the crude enzyme. The amount (mg) per unit of activity (U) of enzyme can easily be increased, even with the purified preparations that are commercially available.

To achieve these goals, the choice of enzyme support and the binding chemistry should be optimized. Small particle diameter and small pore sizes will result in large specific surface areas, which are important for high enzyme loading and low additional

band-broadening. All these factors have to be optimized empirically since they are difficult to predict and determine theoretically.

## Amperometric Biosensors

A general definition of a biosensor is a system of two transducers, biochemical and physical, in intimate contact, where there is a stoichiometric relation between the concentration of the analyte and the electrical signal. The biochemical transducer converts the analyte into a chemical or physical property, which is sensed and converted into an electrical signal by the physical transducer. Enzymatic redox reactions are particularly closely related to electrochemical transducers since an electron transfer step is involved in the natural cycle of the redox enzyme. The coupling is, however, far from straightforward. All redox enzymes depend on a cofactor as the natural partner in the exchange process.

The physical combination of immobilized enzymes and electrodes can be realized in several different ways. The most common are those in which the enzyme is immobilized in a membrane that is held in close proximity to the electrode surface, immobilized directly on the electrode surface with retained activity, or immobilized in an electrically conducting paste comprising a carbon-oil mixture, known as a carbon paste electrode. The enzyme substrate (and cosubstrate, if required) will diffuse from the

solution to the electrode surface, reach the enzyme, and undergo the appropriate reaction. The reaction product will then diffuse to the electrode surface, where the actual analytical reaction will take place. A membrane is often deposited onto the electrode surface. This membrane can be used as a matrix, the material support for a proper immobilization. It can also be used as a barrier to protect the enzyme from interfering compounds present in the sample. The selectivity of the membrane can in the latter case be controlled by electrostatic shielding, using charged membranes and/or by a size exclusion effect controlled by the pores in the membrane. Optimal membranes should adhere well to the surface of the electrode, and they should be thin, hydrophilic, and porous. Cellulose acetate, cellulose nitrate, poly(vinyl alcohol), and polyurethane are examples of commonly used enzyme membranes.

## Immobilized Enzymes in Analytical Flow Systems

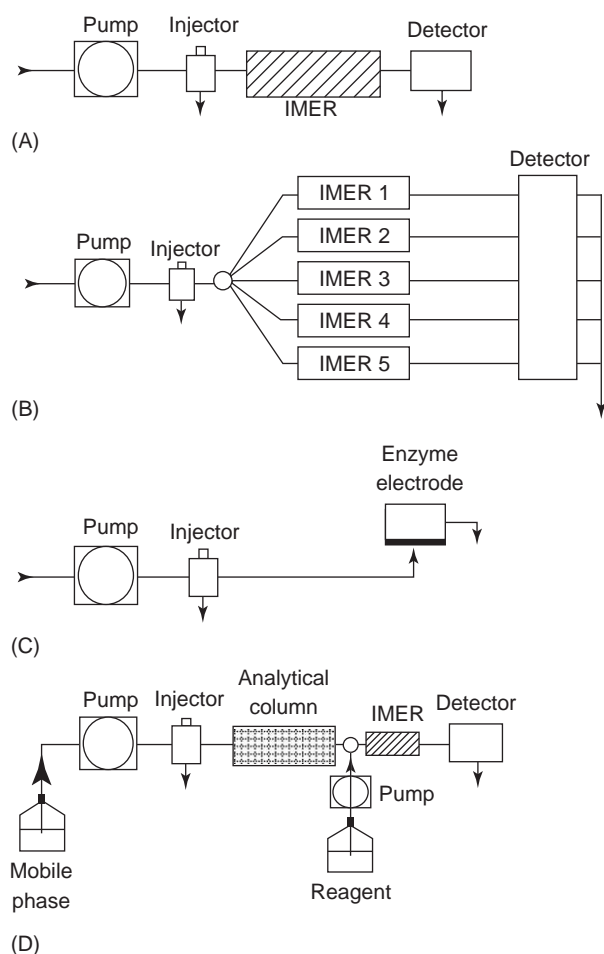

The amount of enzyme that can be immobilized and contained in a reactor of moderate size (5–500  $\mu$ l) is very large (up to 1000 U). Thus, when a solution containing the enzyme substrate passes through the reactor, equilibrium of the enzymatic process can be reached. In many cases, the equilibrium strongly

**Figure 3** Flow injection and liquid chromatographic flow configurations using immobilized enzymes: (A) single immobilized enzyme reactor (IMER) in a flow injection system; (B) multiple immobilized enzyme reactors in a flow injection system; (C) system with enzyme electrode; and (D) postcolumn liquid chromatography system with reagent flow and immobilized enzyme reactor.

favors the product side (chemically irreversible reaction), which means that virtually 100% of the substrate can be converted into a detectable product. This is never the case with an enzyme electrode, where the amount of immobilized enzyme in the membrane or on the electrode surface is more restricted. It will usually be too low ( $1\text{--}3\text{ U cm}^{-2}$ ) to achieve equilibrium of the catalyzed reaction within a reasonable time, particularly when used in a flowing solution. With a reactor containing excess enzyme, slight variations in the flow rate, pH, ionic strength or temperature, and the presence of small concentrations of inhibitors and activators will not affect the conversion efficiency of the reactor.

Nevertheless, both immobilized enzyme reactors and biosensors are used as detection units in flow injection analysis and liquid chromatography. Some of these flow systems are illustrated in Figure 3. The choice of flow system will be determined both by the number of analytes to be measured and by the complexity of the sample. Flow injection in combination with immobilized enzymes is used for single solute determinations, as in the systems shown in Figure 3A–C. Multiple solute determination requires a separation step whereby the chromatography column is introduced (Figure 3D). There is also an additional need for separation power when interfering matrix components in complex samples need to be eliminated in order to permit accurate quantitation of the analyte. The use of multiple flow lines with immobilized enzyme reactions in flow injection systems has been demonstrated, whereby each flow line measures a

single analyte in the sample. This approach has an efficiency similar to that obtained using chromatographic separation.

Immobilized enzymes are used to detect many different solutes in analytical flow systems (Table 1). Among the most common targets are glucose (detected with immobilized glucose oxidase), acetylcholine and choline (acetylcholine/choline oxidase), lactate (lactate oxidase or dehydrogenase), and pyruvate (pyruvate oxidase). The types of applications range from those involving relatively clean matrices to those involving complex samples such as clinical tests (e.g., blood, urine), food, feed, water, and environmental specimens.

## Carrier-Free Systems

The use of a carrier or polymeric matrix to immobilize enzymes introduces a large noncatalytic component into the system which has the potential to interfere with the catalytic properties of the enzyme and reduce its activity compared to the same mass of free enzyme. Although this disadvantage is balanced by the reusability of immobilized enzymes, it would be even more beneficial if the activities of immobilized enzymes could match those of free enzymes. Carrier-free systems, in which enzyme molecules are linked to each other to form large complexes, may provide a solution to this problem. In a carrier-dependent system, up to 99.9% of the mass is taken up by the noncatalytic matrix. In noncarrier systems, 100% of the complex has the potential to retain catalytic activity.

**Figure 4** The different approaches to the production of carrier-free immobilized enzymes; (A) crystallization; (B) aggregation; (C) spray-drying; and (D) direct cross-linking. AGG, aggregates; CLE, cross-linked dissolved enzyme; CLEA, cross-linked enzyme aggregate; CLEC, cross-linked enzyme crystal; CSDE, cross-linked spray-dried enzyme; CRY, crystals; SDE, spray-dried enzyme.

The simplest way to achieve carrier-free immobilization is to cross-link enzymes in solution. However, the success of this process is highly dependent on the ambient conditions (temperature, pH, etc., which must be established empirically) and often results in an unacceptable loss of activity. Furthermore, the gelatinous complexes formed in this manner can be difficult to handle. Some degree of control may be introduced by cross-linking the enzymes within a gel matrix or following adsorption to a membrane, but this reintroduces a carrier into the system, and hence increases the noncatalytic mass and reduces the efficiency. Alternatives to the in-solution cross-linking strategy include the prior formation of enzyme crystals or aggregates, which are much more stable, easier to handle, and retain a higher level of activity. Several cross-linked crystals are used in commercial catalysts, mainly for stereospecific synthesis reactions. Enzymes may also be spray dried prior to cross-linking, but such complexes tend to show a relatively low activity compared to crystals and aggregates. The methods for preparing carrier-free immobilized complexes are shown in Figure 4.

## Introduction

Electrochemical sensors are appropriate for the determination of different gases (e.g., oxygen, hydrogen, and carbon dioxide), nitrogen compounds (e.g., NO<sub>x</sub> and NH<sub>3</sub>), ion activities (alkali and heavy metals), and oxidizable and reducible organic substances down to the submicromolar concentration

range. The determination of many other important substances requires the coupling of sensors with a chemical or biochemical reaction to generate an electroactive product.

A problem of paramount importance to analytical chemistry is selectivity, particular at trace concentrations where potential interferents might be present at higher concentrations than the analyte. Enzymes allow the determination of trace concentrations even in complex media due to their excellent chemical selectivity, thus avoiding the need to use highly sophisticated instrumental techniques such as chromatography or mass spectrometry. Furthermore, when enzymes are employed as tracers in binding assays using antibodies, binding proteins, lectins, etc., the inherent chemical amplification properties of the enzyme's catalytic activity can be fully exploited

to realize extremely sensitive assay methods. In addition, biologically related parameters such as taste, odor, fatigue substances, mutagenicity, and nutrient content are quantifiable by using multienzyme systems, intact organelles, or cells.

## Development of Enzymatic Measurements

Enzymes accelerate the attainment of equilibrium of chemical reactions by a factor of  $10^6$ – $10^{12}$  as compared with uncatalyzed reactions. Several enzymes, e.g., catalase, acetylcholinesterase, and fumarase, have achieved virtual catalytic perfection approaching the diffusion-controlled limit. Thus, the splitting of  $H_2O_2$  is accelerated by a factor of  $3 \times 10^{11}$  in the presence of catalase.

Traditionally, enzymes have been used as analytical reagents to measure substrate molecules by catalyzing the turnover of these species to detectable products. In addition, groups modifying the rate of the enzyme reaction – activators, prosthetic groups, inhibitors, and also enzymes themselves – are accessible to measurement.

To simplify early enzymatic measurements the principle of litmus paper was adopted – a filter paper was impregnated with the analyte-converting enzymes and coreactants. Enzyme ‘test strips’ for the determination of more than 15 different metabolites and enzymes are commercially available. In the early 1960s, Clark introduced a new sensor concept of the ‘enzyme electrode’. He placed an enzyme solution (an oxidase) immediately in front of an oxygen electrode and prevented loss of the enzyme by dispersion into the background solution by covering the reaction chamber with a semipermeable membrane. The same enzyme preparation could then be used for several samples. The next stage was reached in 1967 by Updike and Hicks, who entrapped the enzyme in a gel, thus increasing the working stability and simplifying the sensor preparation. In 1975, Yellow Springs Instruments Co. (USA) commercialized a glucose analyzer that was based on Clark’s invention.

The choice of the ‘indicator electrode’ is largely determined by the species involved in the sensing reaction. Oxygen and  $H_2O_2$ , which are the cosubstrate and product of oxidases, as well as NAD(P)H, the cosubstrate of  $\sim 300$  pyridine nucleotide-dependent dehydrogenases, can be determined amperometrically. Hydrolases are mostly coupled to ion-selective electrodes. Based on these principles, many enzyme sensors have been developed and commercialized (Table 1).

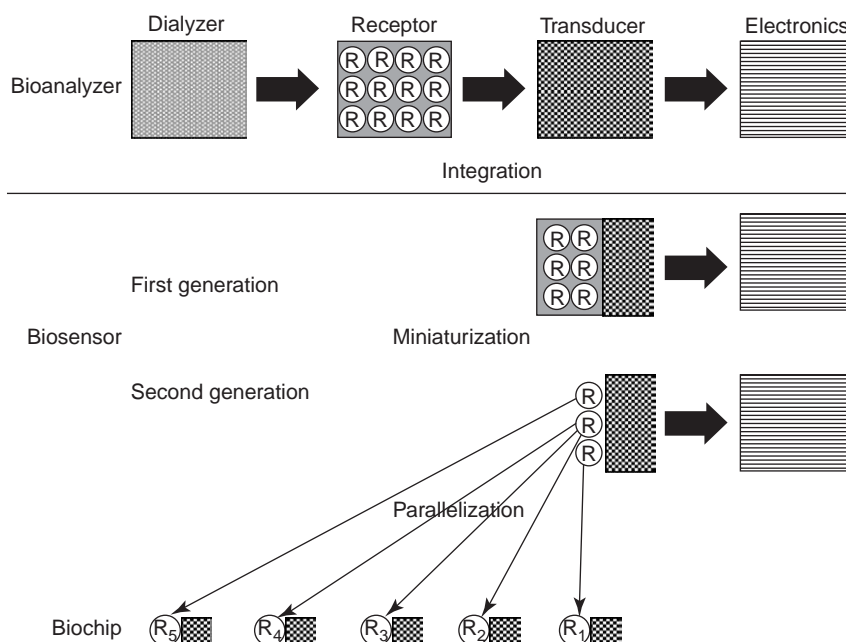

**Table 1** Coupling of enzymes with electrochemical sensors in enzyme electrodes

	$I^-$	
	$F^-$	

IUPAC proposed a definition of a biosensor in 2001: “An electrochemical biosensor is a self-contained integrated device which is capable of providing specific quantitative or semi-quantitative analytical information using a biological recognition element (biochemical receptor) which is in direct spatial contact with a transduction element. A biosensor should be clearly distinguished from a bioanalytical system which requires additional processing steps, such as reagent addition. A device that is both disposable after one measurement, i.e., single use, and unable to monitor the analyte concentration continuously or after rapid and reproducible regeneration, should be designated a single use biosensor.”

According to their level of integration, the enzyme electrodes described in the literature can be subdivided into three generations. In the simplest approach (first generation) the biocatalyst is entrapped between or bound to membranes and this arrangement is fixed at the surface of the transducer. The immediate adsorptive or covalent binding of the biocatalyst at the electrode surface or the inclusion within the electrode body permits the elimination of semipermeable membranes (second generation). The direct binding of the biocatalyst to the transducer is the basis for further miniaturization. Independently addressable microelectrodes or ion-selective field-effect transistors (ISFETs) are the transducer units of these electrochemical biochips that allow for the ‘parallel’ determination of a broad spectrum of analytes (Figure 1).

**Figure 1** Generations of biosensor technology.

A typical example of the first generation would be a glucose or lactate electrode comprising the appropriate oxidase entrapped in or bound to a membrane that is fixed at an oxygen or hydrogen peroxide detecting electrode and covered by a semipermeable membrane.

The 'membrane' directed toward the (usually ideally mixed or flowing) measuring solution fulfills a number of functions. First, it provides the sensor with a certain degree of selectivity. The pore size and, perhaps, charge permits the exclusion of deleterious or interfering molecules, such as proteins or electroactive compounds and may provide useful partitioning of other compounds. Furthermore, the thickness and pore size permit us to affect the measuring range of the sensor by controlling the actual rate of reagents reaching the reaction layer.

After permeation of analyte, cosubstrates, and effectors through the membrane to the underlying enzyme layer the analyte is converted therein with formation or consumption of a detectable species. In the illustrated case this is the formation of a reduced mediator or cosubstrate (e.g., hydrogen peroxide from oxygen) that is oxidized at the electrode or the generation of protons. The enzyme membrane is characterized by 'enzyme loading' reflecting the interplay of enzyme kinetics and mass transport. The loading is crucial for the response characteristics and the stability of the sensor whereas the choice of enzyme determines the chemical selectivity of the measurement.

## Combination of Electrodes with Immobilized Enzymes

### Immobilization of Enzymes on Electrodes

To allow the repeated use of enzymes, cells, and other biologically active agents in analytical devices, numerous techniques have been developed for their fixation. In many cases the enzyme is stabilized by immobilization and so may easily be separated from the sample. Its stable and largely constant activity makes the enzyme an integral part of the analytical device. Methods to immobilize enzymes entail physical and chemical techniques and a combination thereof. The primary physical methods are adsorption direct to the electrode and entrapment in water-insoluble polymeric gel. Chemical immobilization is effected by covalent coupling to reactive groups at the transducer surface or by intermolecular cross-linking of the biomolecule using bifunctional reagents.

Structured deposition of enzymes on the surface of microelectrodes or ISFETs is a major problem during mass production. Layers of polymers, e.g., polypyrrole or polyaniline, are deposited on conducting areas by electropolymerization. Biomolecules are either entrapped in the polymer matrix while the layer is being formed or are coupled to the layer via specific chemical reactions. The structuring of a uniform layer containing a biocomponent is possible when passive regions are photodeactivated. Alternatively,

enzymes are deposited only at the sensitive region by using an enzyme solution in a photoresist.

Using these microspotting techniques the active areas of arrays are covered with different receptor molecules or cells.

### Transfer of the Chemical Signal from the Enzyme to the Electrode

The high selectivity of enzyme electrodes is well recognized in the literature. Prerequisites for the selectivity are (1) the high selectivity of the biocatalyst and (2) interference-free electrochemical indication of the reaction product. With regard to selectivity, two groups of enzymes are available in nature as analytical reagents: (1) group-specific enzymes converting a family of analogous substances and (2) enzymes possessing high chemical selectivity that allows them to discriminate even between stereoisomeric compounds.

Amperometric enzyme electrodes are at the leading edge of biosensors as far as the body of scientific publications as well as the development of the commercially available devices is concerned. Only a few conductimetric enzyme electrodes and EN(zyme)-FETs have been described.

Ion-sensitive electrodes based on ion exchangers or neutral carriers (e.g., nonactin, valinomycin) have been coupled with ammonia-liberating enzymes, e.g., urease and creatininase, and amino acid oxidases to build probes for urea, creatinine, and different amino acids. The most important ion-selective electrode using a 'solid membrane' is the glass electrode for pH measurement. By combination with enzymes that catalyze reactions that change the pH (especially hydrolases, e.g., urease, penicillinase), sensors are obtained for the respective substrates. Despite their selectivity for hydrogen ions their applicability is restricted because changes in the sample buffer capacity may affect the indicated pH signal. The formation or consumption of ammonia or carbon dioxide in the enzyme-catalyzed substrate conversion can be indicated by membrane-covered pH glass electrodes. The membranes allow the permeation of gases from the enzyme layer into the buffer-containing layer adjacent to the pH sensor. To obtain sufficient sensitivity the pH of the measuring solution should be above 9 and below 5 for indication of ammonia and carbon dioxide, respectively. Generally, these pH values differ substantially from the pH optima of deaminases and decarboxylases. Therefore, for the respective enzyme electrodes a compromise pH has to be found or the enzyme reaction has to be spatially separated from the potentiometric indicator and pH shift included between them (reactor electrode).

Platinum oxide and iridium oxide probes have been coupled to immobilized enzymes to give miniaturized biosensors. Furthermore, to construct microbiosensors, ISFETs sensitive to hydrogen or fluoride ions have been covered with a layer of enzyme. The light-addressable biosensor indicates the photocurrent generated by illumination of the rear by an array of light-emitting diodes. The signal reflects the local pH or redox potential at the surface. In this way, changes of the surface potential caused by enzyme reactions, microorganisms, or the action of receptors can be measured with high sensitivity.

In order to eliminate erroneous readings due to differences of the sample pH, dual sensor systems have been developed that use one enzyme-loaded pH sensor and one blank sensor as a reference. Problems arise due to independent fluctuations of the sensor's characteristics and changes in buffer capacity of the sample, which cannot be compensated for by this arrangement. The 'pH-stat' enzyme sensor circumvents this interference. The hydrogen or hydroxyl ions generated in the enzyme reaction are consumed by water electrolysis. The charge necessary in order to maintain a constant pH represents the amount of ions formed and it is independent of the buffer capacity. The device contains, in addition to the enzyme-covered pH FET, a pair of amperometric electrodes for oxygen or hydrogen generation, which are controlled by an on-chip pH-stat coulometer system.

Oxygen and hydrogen peroxide, which are the cosubstrate and product, respectively, of oxidase catalyzed reactions, as well as NAD(P)H, the coenzyme for ~300 dehydrogenases, can be determined amperometrically. The Clark-type oxygen electrode can detect oxygen or hydrogen peroxide. Furthermore, artificial redox mediators, such as hexacyanoferrate(III), *N*-methylphenzinium sulfate ( $\text{NMP}^+$ ), ferrocene, and benzoquinone, are suitable electroactive reaction partners. The electrode potential is decisive for the selectivity of the sensor. Any electroactive substance being converted at lower potential than hydrogen peroxide contributes to the total current. Thus, at an electrode potential of +600 mV for hydrogen peroxide measurement, ascorbic acid is also oxidized. Such interferences may in part be eliminated by covering of the anode with a thin, anion-bearing membrane, such as cellulose acetate. Alternatively, the difference between the signal obtained from a naked reference electrode and an enzyme-loaded sensor can be measured. In spite of these problems, enzyme electrodes based on oxidases combined with amperometric hydrogen peroxide measurement are still the most common type of enzyme electrodes.

To eliminate interferences by co-oxidizable sample constituents, the electrode potential is kept as low as possible. Therefore, the reaction partner chosen to be electrochemically indicated should be the one that is converted at the lowest possible potential. The natural electron acceptors of many oxidoreductases, for example, methanol dehydrogenase, alcohol dehydrogenase, and cytochrome  $b_2$ , and glucose, lactate, pyruvate, glycolate, sarcosine, and galactose, oxidases can be replaced by electron mediators, e.g., hexacyanoferrate(III),  $NMP^+$ , ferrocene, and benzoquinone. With these mediators an electrode potential of  $\sim +200$  mV can be applied; this decreases the interference of ascorbic acid and also enables such enzymes to be coupled with electrodes in oxygen-free solution. For this reason chemically modified electrodes, where the mediator is integrated with the amperometric electrode, have been combined with immobilized, mediator-dependent enzymes. In the simplest approach the solid mediator was introduced in crevices of a carbon electrode body and a dialysis membrane used to prevent it from leaching out. In the next stage of development the mediator was mixed with the carbon paste of the electrode body. Finally, all reagents – enzyme, mediator, and cofactor – were integrated into the top of the electrode.

As with mediators, enzymes may be bound covalently to the electrode surface, thus producing enzyme-chemically modified electrodes. Adsorption of redox polymers containing benzoquinone or heavy-metal ion complexes at carbon electrodes results in the catalysis of the electron transfer by ‘wiring’ the enzyme molecules to the electrode. When enzymes and mediators are co-immobilized at the surface or within the electrode, addition of auxiliary substances during the measuring process can be avoided; thus a reagentless measuring regime becomes feasible. An alternative to the application of mediators is direct electron transfer between the prosthetic group of the enzyme and the redox electrode.

Heterogeneous electron transfer reactions have been realized with more than 50 different proteins, mainly electron transferases, and also substrate-converting oxidoreductases. At bare metal electrodes irreversible adsorption accompanied by denaturation prevents a fast electron transfer to the protein molecules. Adsorption of modifiers that promote an appropriate orientation of the protein results in a facilitated direct electron transfer with different redox enzymes, for example, cytochromes and ferredoxins.

A symbiosis of mediated and direct electron transfer is the covalent fixation of electron-tunneling relays to the protein moiety of oxidoreductases.

The use of an electrode reaction offers the possibility to affect the enzyme reaction. In the oxygen-stabilized enzyme electrode the influence of the oxygen content of the sample solution is eliminated. For this purpose the same amount of oxygen as is consumed in the enzyme reaction is generated at a net electrode arranged within the enzyme layer. By using voltage pulses instead of a constant potential, both sensitivity and specificity of microenzyme electrodes can be improved.

## Measurable Analytes and Analytical Characteristics

Electrochemical enzyme sensors for  $\sim 140$  analytes have been described. Among them are low (relative) molecular mass substances (metabolites, drugs, nutrients, gases, metal ions, coenzymes, enzyme activators, and vitamins) as well as macromolecules (enzymes, lectins, nucleic acids, polymeric carbohydrates like starch and cellulose), viruses, and microorganisms. The analytes may be roughly subdivided as follows:

- Carbohydrates: amygdalin, cellobiose, cellulose, fructose, galactose, glucose, glucose-1-phosphate, glucose-6-phosphate, lactose, maltose, pullulane, starch, sucrose.
- Steroids: androstenedione, cholestenone, cholesterol, cholesterol esters, testosterone.
- Alcohols and carboxylic acids: acetate, ascorbate, benzoate, benzoquinone, catechol, chlorophenol, ethanol, fatty acids, formate, glycerol, gluconate, glycolate, glyoxylate, hexanol, hydroquinone, hydroxybutyrate, isocitrate, lactate, malate, methanol, oxalate, phenol, phosphoenolpyruvate, pyruvate, succinate, salicylate.
- Nitrogen compounds: acetylcholine, aminopyrine, aniline, bilirubin, cadaverine, caprolactam, epinephrine, guanosine, hypoxanthine, inosine, lecithin, monoamines, penicillin, spermine, spermidine, theophylline, urea, uric acid, xanthine.
- Amino acids: alanine, asparagine, aspartate, cysteine, glutamate, glutamine, glutathione, histidine, iso-leucine, leucine, lysine, methionine, phenylalanine, sarcosine, serine, tryptophan, tyrosine, valine.
- Cofactors: AMP, ADP, ATP, FAD, IMP,  $NAD^+$ , NADH,  $NADP^+$ , NADPH, hydrogen peroxide, pyridoxal phosphate, thiamine pyrophosphate.
- Proteins, peptides, and enzymes:  $\alpha$ -amylase, angiotensin, arginase, asparatame, cholinesterase, creatine kinase, glucoamylase, serum albumin, lactate dehydrogenase, peroxidase, pyruvate kinase, transaminases, alkaline phosphatase,  $\beta$ -galactosidase.

- Gases: CH<sub>4</sub>, CO, CO<sub>2</sub>, H<sub>2</sub>, NH<sub>3</sub>, NO, O<sub>2</sub>, SO<sub>2</sub>.
- Inorganic ions: cadmium, copper, fluoride, manganese, mercury, nitrate, nitrite, phosphate, sulfate, sulfide, sulfite, zinc, cyanide.

The signal-concentration dependence, i.e., measuring range, for electrochemical biosensors is linear over between one and three concentration decades. The lower limit of detection is  $2 \times 10^{-4} \text{ mol l}^{-1}$  with potentiometric electrodes and  $1 \times 10^{-8} \text{ mol l}^{-1}$  with amperometric monoenzyme electrodes. The use of the amplification reactions permits the detection limit to be decreased below the nanomole per liter range. Whereas the response time of potentiometric enzyme electrodes averages 2–10 min, with amperometric electrodes an assay can be conducted from within a few seconds up to one minute. This permits up to several hundred determinations per hour to be performed. Increasing complexity of the biochemical reaction system, e.g., by use of coupled enzyme reactions, brings about an increase in the overall measuring time.

Usually the imprecision found with enzyme electrodes ranges from 0.5% to 5%, which is, of course, dependent on the analytical setup used (e.g., manual sample injection versus flow injection). The lifetime of enzyme electrodes depends on several factors including the specific enzyme activity, the eventual formation of inactivating reaction products, and the operation conditions of the sensor. Generally, a high enzyme excess in the biocatalytic membrane is desirable in order to obtain a high stability. Lifetimes are in the range of several days or months, or between some hundreds and several thousand measurements.

## Coupled Enzyme Reactions in Enzyme Electrodes

Since not all enzyme-catalyzed reactions involve compounds detectable at an electrode, such as hydrogen ions, oxygen, or hydrogen peroxide, only a limited number of substances can be determined with one-enzyme sensors. In order to broaden the range of measurable substances, coupled enzyme reactions for analyte conversion in enzyme electrodes have been devised. In 'enzyme sequences' the primary product of the analyte conversion is further converted enzymatically with the formation of a measurable secondary product or reaction effect. On this basis, families of electrodes have been developed, which combine glucose-, lactate-, or alcohol-producing primary enzyme reactions with the respective oxidases. Such enzyme sequence electrodes are known for sucrose, lactose, maltose, glucose itself, gluconate, glucosinolate, bilirubin, ATP, glucose-6-phosphate,

cholesterol esters, fatty acid esters, acetylcholine, creatine, hypoxanthine, glycerol, lactate, pyruvate, inosine.

The application of 'competition' schemes realized by coupled enzyme reactions also provides access to analytes not determinable with the usual enzyme electrodes. Here the analytical information is gained either from the competitive action of two enzymes, of which one produces the signal, on the same substrate; or from the competition of the analyte with the substrate for the same (signal-generating) enzyme, the latter approach resembling that of inhibitor determination.

The coupling of enzyme pairs in recycling schemes provides a means for signal amplification, i.e., the enhancement of the sensitivity of enzyme electrodes. This method works analogously to the cofactor recycling known from biochemical analysis using dissolved enzymes. In a bienzyme electrode the analyte (lactate) is converted in the reaction of enzyme 1 (lactate oxidase) to a product (pyruvate), which is the substrate of enzyme 2 (lactate dehydrogenase). The latter catalyzes the regeneration of the analyte that thus becomes available for enzyme 1 again, and so forth. One of the coreactants (e.g., oxygen) is detectable directly or via additional reactions. (It is evident that the terms 'analyte' and 'product' are interchangeable here; this may be useful, but may also cause problems in real samples.) If enzyme 1 is present in sufficiently high concentration to ensure diffusion control, signal amplification is achieved by switching on enzyme 2 by addition of its cosubstrate (i.e., NADH). In such systems the analyte acts as a catalyst, being shuttled between both enzymes in the overall reaction of both cosubstrates. In this way significantly more cosubstrate will be converted than analyte is present in the enzyme membrane. Hence, the change in the parameter indicated at the electrode will greatly exceed that obtained with one-way analyte conversion. The ratio of the sensitivity in the linear measuring range of the amplified and the unamplified regime is termed the amplification factor. According to theory, the amplification factor  $G$  is given by

$$G = k_1 k_2 L^2 / 2(k_1 + k_2)D$$

where  $k_1$  and  $k_2$  are kinetic parameters,  $D$  is the diffusion coefficient of the analyte, and  $L$  is the membrane thickness.

Specifically in enzyme electrodes, where the sensitivity limit is determined by diffusion, the use of analyte recycling gives rise to a sensitivity enhancement by overcoming just this limit. On the other hand, the upper limit of the linear measuring range is decreased. Furthermore, since the enzyme excess

present in the membrane is included in the analyte conversion, the amplification factor will decrease with progressive enzyme inactivation during operation of the sensor.

Enzyme electrodes based on analyte recycling have been developed for the following compounds: lactate, pyruvate, glucose, gluconolactone, NADH,  $\text{NAD}^+$ , ethanol, benzoquinone, hydroquinone, ADP, ATP, glutamate, and malate. Depending on the enzymes and membrane materials used, amplification factors range from 3 to 48 000. Detection limits down to  $50 \text{ pmol l}^{-1}$  have been achieved. However, when dealing with extremely high amplification it should be borne in mind that the sensor signal becomes highly susceptible to minute amounts of contaminants affecting the enzyme reactions or the diffusion of the reactants.

Another coupling principle used for amplifying the response of enzyme electrodes is based on 'biocatalytical preconcentration' of intermediates. The method relies on an enzyme sequence. In the first step of the measurement the conversion of the analyte (glycerol) by the first enzyme (glycerol dehydrogenase) is permitted to proceed for a certain time (usual to equilibrium) during which an intermediate (NADH) accumulates in the enzyme layer. Then the second step, the actual measurement, is initiated by addition of an excess of cosubstrate (pyruvate) of the indicator enzyme reaction (lactate dehydrogenase + lactate monooxygenase). The conversion of the accumulated intermediate results in increased oxygen consumption. This method leads to amplification between 2- and 60-fold and has been used in the determination of glucose, glucose-6-phosphate, hypoxanthine, formate, glycerol, and  $\text{NADP}^+$ . It is applicable to all analytes being converted in sequential enzyme systems, provided the terminal reaction depends on a cofactor and leads to an electrochemical signal.

The selectivity of enzyme electrodes can be improved by means of another coupling principle that is capable of filtering chemical signals by eliminating interferences of the enzyme or electrode reaction caused by constituents of the sample. Compounds that interfere with signal transduction, e.g., ascorbic acid with anodic oxidation of hydrogen peroxide, can be transformed into inert products by reaction with an eliminator or 'anti-interference' enzyme (e.g., ascorbate oxidase). Since the conversion of analyte and interferent proceed in parallel, both the eliminator and the indicator enzyme may be co-immobilized in one membrane. On the other hand, constituents of the sample that are at the same time intermediates of coupled enzyme reactions can be eliminated before they reach the indicator enzyme layer. For this purpose several different enzyme

membranes have to be used. Of particular importance are enzymatic anti-interference systems for glucose because this compound is contained in most real samples where di- and polysaccharides have to be determined with enzyme sequence sensors based on glucose oxidase as indicator enzyme. Systems have been devised to eliminate lactate, ascorbic acid, ammonia, and oxygen.

In general, enzymes to be used in multienzyme electrodes should fulfill the following requirements:

- Their pH optima should be reasonably close to each other and to that of the indicator reaction.
- They should not be inhibited by necessary cofactors, effectors, or intermediates.
- Their cofactors or effectors should not react with each other.

## Application of Enzyme Electrodes

The most relevant fields of practical application of enzyme electrodes are medical diagnostics, followed by process control, food analysis, and environmental monitoring. The first commercial enzyme electrode-based analyzer (1975) was developed to meet the high demand for glucose determination in the blood of diabetic patients. Since 1975, analyzers for ~12 different analytes have been commercialized. As compared with conventional enzymatic analysis, the main advantages of such analyzers are the extremely low enzyme demand (a few milliunits per sample), their simplicity of operation, the high sample throughput rate, and high analytical quality.

In the medical field a trend toward hand-held devices based on either reusable or disposable glucose and lactate enzyme electrodes for home control of diabetics and for onsite monitoring of surgery and exercise is evident.

The selective determination of blood glucose is of extraordinary importance for the screening and treatment of diabetes. Johnson & Johnson, which is currently the market leader in blood glucose self-testing, launched its first biosensor product – the FastTake<sup>TM</sup> system – in April 1998. All the biggest suppliers in this market now sell biosensor-based products. Abbott Laboratories market ExacTech<sup>TM</sup>, Precision QID<sup>TM</sup> ranges, and recently Sof.Tact; Bayer the Glucometer<sup>TM</sup>, Elite, and Esprit; and Roche Diagnostics the Accu-check Advantage<sup>TM</sup>.

A remarkable new product is the FreeStyle<sup>TM</sup> glucose measuring system from TheraSense Inc. Because of the capillary-type sensor and coulometric measuring principle a 300 nl drop of whole blood is sufficient for one test. Even less painful is the ionophoretic detection with the GlucoWatch<sup>TM</sup>

automatic glucose biographer from Cygnus. This device controls blood glucose over range of  $2.2\text{--}22.2\text{ mmol l}^{-1}$  ( $40\text{--}400\text{ mg dl}^{-1}$ ) for up to 12 h using a single-point calibration. The automatic, frequent, and noninvasive measurements provide more information about glucose levels than the current standard of care.

For a continuous *in vivo* monitoring of glucose long-term stability, selectivity and sensitivity in the millimolar range is needed. To address these problems mass-transport limiting layers were assembled on  $250\text{ }\mu\text{m}$  diameter gold wires coated with glucose oxidase and redox polymer. The multiple sequential adsorption of polyanions and polycations results in an increase of dynamic range up to  $30\text{ mmol l}^{-1}$  glucose and at the same time a reduction of interferants. When a sufficient number of layers were applied glucose could be monitored over several hours. Extremely fast responding glucose sensors with sub-micrometer tip diameter have been constructed by using platinum-deposited flame etched carbon fiber electrodes additionally coated with glucose oxidase.

Other important analytes in medical diagnostics for which enzyme electrodes appear well suited are urea (for dialysis monitoring), uric acid, lactate, and enzyme activities, particularly transaminases and cholinesterase.

In process control and the food industry enzyme electrodes are employed mainly for the determination of carbohydrates, ascorbic acid, amino acids, and penicillin. However, the application of such sensors *in situ* in bioreactors is associated with significant difficulties:

- The sensor has to be sterilized, which, up to now, is virtually impossible.

- Calibration has to be performed by discrete measurements or *in situ*.
- Often the analyte concentration exceeds the linear range of the sensor.
- Various interfering compounds have to be dealt with.
- Thermal and mechanical stress inactivate the sensor.

Environmental control benefits from enzyme electrode-based measurements of toxic compounds, such as heavy metals, fume from organic wastes and pesticides in water, air, and soil.

### Introduction

Enzymes are proteins with catalytic activity, and many are holoenzymes, which are conjugated proteins, such as glyco-, hemo-, metallo-, and flavoproteins. Enzyme-catalyzed metabolic reactions take place in complexes of the enzyme with the reactants (substrates). The concentration of such complexes at any moment is dependent on the concentrations of

the enzyme and its substrate and the affinity of the enzyme for the substrate (Michaelis constant,  $K_m$ ). Measurements of enzyme activities (in micromoles per minute) in human body fluids are essential in clinical chemistry for diagnosis of diseases. The diagnosis is based on the fact that the activity of a particular enzyme in the fluids reflects the concentration of all enzyme molecules, inactive as well as active, which are released from damaged tissues or tumors. Therefore, the determination of enzyme concentrations (milligrams per liter) is of importance in providing a reference point for the measurement of enzyme activity. Though more than 800 kinds of enzyme responsible for

## Enzymes in Physiological Samples

**N Kiba**, University of Yamanashi, Takeda, Kofu, Japan

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Enzymes are proteins with catalytic activity, and many are holoenzymes, which are conjugated proteins, such as glyco-, hemo-, metallo-, and flavoproteins. Enzyme-catalyzed metabolic reactions take place in complexes of the enzyme with the reactants (substrates). The concentration of such complexes at any moment is dependent on the concentrations of

the enzyme and its substrate and the affinity of the enzyme for the substrate (Michaelis constant,  $K_m$ ). Measurements of enzyme activities (in micromoles per minute) in human body fluids are essential in clinical chemistry for diagnosis of diseases. The diagnosis is based on the fact that the activity of a particular enzyme in the fluids reflects the concentration of all enzyme molecules, inactive as well as active, which are released from damaged tissues or tumors. Therefore, the determination of enzyme concentrations (milligrams per liter) is of importance in providing a reference point for the measurement of enzyme activity. Though more than 800 kinds of enzyme responsible for

metabolic reactions have been found in the human body, among others ~30 kinds of enzyme are of importance in clinical enzymology. Further, among them only several enzymes are of significance in clinical diagnosis and now measured routinely.

In this article, the principles of sample preparation and measurement of the catalytic concentration of enzymes of clinical importance and of the absolute enzyme concentration are discussed.

## Preparation of Samples

Most physiological materials must be processed to obtain the optimal sample for measurement of enzyme activity and enzyme concentration. The treatments are obligatory for obtaining accurate and precise analytical results.

Enzymes are relatively fragile substances, with a tendency to undergo inactivation and denaturation under unsuitable conditions. In handling these materials, the first consideration must always be to avoid inactivation.

Serum from whole blood is used as the sample analyzed in order to obtain accurate analytical results because, with relatively few exceptions, the intracellular concentration of an enzyme greatly exceeds its extracellular value. Centrifugal techniques are most frequently employed for separation of blood. In spite of their general use, no standard recommendations exist regarding the centrifugal force, time, and temperature limits; the generally accepted conditions for 10 ml serum samples are 1500–2000 *g* for 10–15 min at room temperature. Fibrin aggregates are spun down with the blood cells. A sufficient clotting time (not less than 2 h) at room temperature provides clear separation of the clot.

Lymph, cerebrospinal fluid (CSF), and synovial fluid are centrifuged to remove any contaminating blood cells, fibrin, and particulate matter.

Saliva is centrifuged at 10 000 *g* for 30 min in a refrigerated centrifuge. Uncentrifuged saliva is used directly for assay of  $\beta$ -glucosidase (EC 3.2.1.21).

Urine is centrifuged and then dialyzed and gel filtered to remove enzyme inhibitors.

Tears are analyzed without any treatment.

In many cases, minced tissue is extracted with a buffer solution and then centrifuged. In some cases, membrane enzymes that are more firmly bound to the structural framework of mitochondria require special methods; these include drying with acetone, treatment with butanol–water mixtures, extraction of dried mitochondria with various organic solvents, extraction using aqueous solutions of detergents, treatment with chaotropic ions, or exposure to the action of hydrolytic enzymes.

## Measurement of Catalytic Concentration

Enzyme-catalyzed reactions usually follow the rate of appearance of a product or disappearance of a substrate. The catalytic activity of an enzyme is measured in terms of the catalyzed rate of conversion, not rate of reaction; in the physicochemical sense, the unit for the reaction rate is moles per liter per second, whereas for enzyme-catalyzed reactions it is defined by the unit moles per second (this quantity is called a katal (kat)). The activity has until now been expressed in units of micromoles per minute (unit (U) or international unit (IU)). One unit (IU) is  $16.67 \times 10^{-9} \text{ kat} = 16.67 \text{ nkat}$ .

In the measurement of enzyme activity, a high substrate concentration that is greatly in excess of the  $K_m$  value is always used, and the enzyme sample to be investigated is correspondingly diluted; under the conditions, the rate of the enzyme-catalyzed reaction depends only on the enzyme concentration, i.e., it is a zero order reaction. Even under conditions of substrate saturation, the measured catalytic activities are influenced by slight differences in reaction conditions, such as the temperature, composition and concentration of the buffer, pH value, nature of the substrate and its concentration, coenzymes, and protein content in the sample. Therefore, the results of measurement of the catalytic activity of an enzyme are in principle method dependent; direct comparison of the results between laboratories is made difficult by the use of different methods in different laboratories.

## Measurement of Enzyme Activity in Serum

Though various methods for the determination of enzyme activity are used routinely in clinical laboratories, many of them are covered by patents, and the components of their test kits are not commercially available. In clinical chemistry, reference methods and certified enzyme reference materials (enzyme calibrators) for determination of activities of enzymes in human blood serum are recommended by international commissions (ISOTC/212, International Federation of Clinical Chemistry IFCC, Institute for Reference Materials and Measurements EU, etc.) at present for improved accuracy and establishment of traceability chains of the enzyme measurement system. By using these reference materials, the inaccuracy (imprecision between laboratories) has been minimized to within several per cent in several enzymes, such as lactate dehydrogenase (LDH) (EC 1.1.1.27),  $\gamma$ -glutamyltranspeptidase ( $\gamma$ -GT) (EC 2.3.2.2), alanine aminotransferase (ALT) (EC 2.6.1.2), creatine kinase (CK) (EC 2.7.3.2), alkaline phosphatase (ALP) (EC 3.1.3.1), acid phosphatase (EC 3.1.3.2), and  $\alpha$ -amylase (AMY)

(EC 3.2.1.1.). The measuring temperature for reference methods is 30°C. When a result is obtained at a temperature other than 30°C, it should be related to that of the reference method. This can be done by using the reference materials or a temperature conversion factor.

### Measurement of Enzyme Activity in Body Fluids Other than Serum

Measurement of the catalytic activity of enzymes in body fluids other than blood, such as lymph, CSF, saliva, tears, and urine, is used as an aid to clinical diagnosis. Since lymph is recognized as a transport vehicle for enzymes, the lymph-serum ratio of enzyme activity is useful in estimating the origin and fate of a particular enzyme in lymph and serum. Methods usually applied to serum are applicable to measuring enzyme activity in lymph.

The diagnostic potential of measurement of the activity in CSF may not have been fully pursued owing to a certain risk to the patient by the puncture and to the small sample volume.

Saliva and tears can be obtained easily using harmless sampling techniques. Measurement of lysosomal enzymes (mainly hydrolases) in these fluids is applied for diagnosis of enzyme deficiency. Since the activities of many enzymes are comparatively low in their fluids, substrates have been used for fluorimetry, which is more sensitive and selective than spectrophotometry.

Enzymes are physiological constituents of urine, and most of them originate from renal tissue. The measurement of urinary enzymes has not yet been accepted as a routine clinical diagnostic method since urine contains many kinds of enzyme inhibitors and activators that must be removed before measurement of enzyme activity; the most commonly used separation methods are gel filtration and dialysis.

There is as yet no clear evidence that any measurement of the enzyme activity in synovial fluid is useful for diagnosis of disease.

### Methods Following Enzyme Reactions

Today, spectrophotometric methods are almost solely used for determination of the catalytic activities of enzymes in physiological samples in both manual and automated techniques because of their ease, simplicity, and sensitivity. No sampling is required, no reagents are necessary other than the actual reactants, and the result can be obtained with one small sample.

Many substrates and products of enzyme reactions absorb light in the visible region of the spectrum

and/or ultraviolet (UV) region. In spectrophotometric methods, the change in concentration with time (reaction rate) is directly proportional to the change in the absorbance ( $\Delta A$ ) with time ( $\Delta t$ ); the unit of measurement is  $\Delta A/\Delta t$ . These methods are directly applicable to oxidizing enzymes in physiological samples in which the second reactant (hydrogen acceptor) undergoes a change in absorbance on reduction by the substrate; e.g., for dehydrogenases the absorbance changes of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which have an absorption band at 340 nm in the reduced state, not in the oxidized state, and of hexacyanoferrate(III) (420 nm) and dyes such as dichloroindophenol (600 nm) and methylene blue (610 nm), which absorb light in their oxidized forms, can be followed using these methods. Even when there is no absorbance change with the normal substrates, it is sometimes possible to find an artificial substrate that gives absorption changes at a suitable wavelength. For hydrolyzing enzymes such as phosphatases, nitrophenyl derivatives have been widely employed.

Even when none of the reactants or products of the enzyme reaction of interest lends itself to an appropriate absorption change, it is often possible to determine one of these components by adding another enzyme or color reagent that acts on the product of the reaction in such a way as to bring about the change; one of the products of the enzyme reaction is made a substrate or reactant of a second reaction (indicator reaction) that can be followed spectrophotometrically.

By coupling NAD(P)-dependent dehydrogenase reactions with the indicator reaction in which tetrazolium salts are reduced using reduced NAD (NADH) and reduced NADP (NADPH) to formazan in the presence of diaphorase (EC 1.6.4.3), the sensitivity is increased by a factor of  $\sim 2.5$  with respect to measurement at 340 nm.

Manometric methods are convenient and accurate methods for following reactions in which one of the reactants or products is a gas; they are adapted for measurement of the catalytic activity of carbonate hydrolyase (EC 4.2.1.1.) in erythrocytes and salivary glands.

### Applications

**Determination of CK activity** CK catalyzes the reversible *N*-phosphorylation of creatine to form creatine phosphate by  $\text{Mg}^{2+}$ -ATP/ $\text{Mg}^{2+}$ -ADP complexes and thus is an important enzyme regulator of high-energy phosphate production and utilization within contractile tissues. CK occurs predominantly

in striated and smooth muscles, and brain, but erythrocytes, liver, and kidneys display almost no CK activity. Serum CK activity is measured as a sensitive indicator of injuries to the skeletal muscle and myocardium. High levels of serum CK activity are characteristic of acute myocardial infarction, muscular dystrophy, brain damage, and malignant tumors of the gastrointestinal tract, though the level of damage to the skeletal muscle or myocardium may depend partially on lymphatic transport of CK. CK has three isoenzymes (CK-MM, CK-BB, and CK-MB) in cytoplasm and two isoenzymes (sarcomeric and non-sarcomeric) in mitochondria. The diagnosis of each disease is accomplished by interpretation of the isoenzyme data because of their specific tissue distribution.

The activity can be measured spectrophotometrically. An internationally agreed reference method has been developed for routine determination in clinical chemistry.

The reactions in the method are shown in reactions [I]–[III].

The rate of increase in absorbance at 340 nm due to the formation of NADPH is directly proportional to the CK activity. The CK reaction (reaction [I]) is coupled by the auxiliary hexokinase (EC 2.7.1.1) reaction (reaction [II]) to the glucose-6-phosphate dehydrogenase (EC 1.1.1.49) indicator reaction (reaction [III]). In these reactions,  $\text{Mg}^{2+}$  and *N*-acetylcysteine are required as activators to form complexes and a reactivator, respectively. To avoid the inhibition of  $\text{Ca}^{2+}$  and adenylate kinase (EC 2.7.4.3) in serum samples, ethylenediaminetetraacetic acid and di(adenosine-5-) pentaphosphate must be present. The activity in serum sample decreases to 98% of initial value after a week in a refrigerator.

**Determination of  $\gamma$ -GT**  $\gamma$ -GT is a glycoprotein and a membrane-bound enzyme that is located primarily on the outer surface of plasma membrane.  $\gamma$ -GT plays a significant role in the glutathione metabolism and the transfer of the  $\gamma$ -glutamyl moiety to certain amino acids that may be involved in the uptake of amino acids by a cell. The body's  $\gamma$ -GT is present in order of decreasing activity in kidneys (relative activity 100), pancreas (24), and liver (7). The significant elevation of  $\gamma$ -GT activity in serum is

associated almost with hepatobiliary disease, and the activity in urine increases in renal diseases; total  $\gamma$ -GT activities in patients' sera can be regarded as being liver specific. In heavy drinkers without hepatobiliary disease, the levels of activity in blood are kept higher than those of normal subjects.

A well-defined reference method is recommended as the routine method in clinical chemistry.

In this method, an artificial substrate, L- $\gamma$ -glutamyl-3-carboxy-4-nitroanilide ( $\gamma$ -GCNA), and glycylglycine (GG) are used as the donor and acceptor, respectively. Since the product of the reaction, 3-carboxy-4-nitroaniline (CNA), has an absorption maximum at 380 nm and  $\gamma$ -GCNA does not absorb above 410 nm, the activity, which is directly proportional to the amount of CNA liberated per unit time, is measured by monitoring the increase in absorbance at 410 nm.

Under these conditions, the autotransfer reaction of  $\gamma$ -GCNA accounts for 1% of the product formed.

The activity in a serum sample is stable for 1 month in a refrigerator.

**Determination of ALP** ALP catalyzes the hydrolysis of phosphate monoesters such as esters of alcohols, phenols and amines, and inorganic pyrophosphates. ALP occurs in cell membranes throughout most of the tissues of the body. High levels of ALP activity in serum arise from hepatobiliary disease, bone disease, and transient hyperphosphatasemia in children. The value of the  $\gamma$ -GT activity is often useful to differentiate, whether an elevation of ALP activity comes from the liver or the bones; high levels of both suggest liver origin. ALP has many isoenzymes that are useful for laboratory diagnosis.

ALP activity is determined spectrophotometrically using an artificial substrate, 4-nitrophenylphosphate, and 2-amino-2-methyl-1-propanol (A2MP) as a phosphate acceptor and buffer agent. The rate of increase in absorbance at 405 nm due to the formation of 4-nitrophenol is proportional to the ALP activity.

In these measurements,  $\text{Mg}^{2+}$  and  $\text{Zn}^{2+}$  are required as activators because the enzyme is a metalloprotein and the activity is stimulated by  $\text{Mg}^{2+}$  and ALP contains a less tightly bound zinc atom that is involved in the catalytic process.

The activity in a serum sample is stable for 1 week in a refrigerator.

**Determination of LDH** Lactate dehydrogenase (LDH) catalyzes the equilibrium reaction of pyruvate to lactate. The activity of serum LDH is due to the presence of the enzyme released from damaged organs and tissues such as liver, heart, skeletal muscle, erythrocytes, etc. because LDH is located in the cytoplasm of the cells. Therefore, the activity of LDH is useful for screening for the existence of cell injuries, estimation of damaged tissues, and evaluation of treatment of diseases. LDH has five isoenzymes, and their patterns are of diagnostic importance.

The LDH activity is measured by determining spectrophotometrically the amount of NADH formed.

The amount of L-lactate oxidized per unit time, indicated by the continuous increase in absorbance at 340 nm due to the reduction of NAD, is directly proportional to the LDH activity. The measurement has to carry out in an alkaline medium and at relative high concentrations of lactate and NAD to obtain reasonable reaction velocities for accurate readings because the reverse reaction is strongly favored.

The activity in serum sample decreases to 97% of the initial value in a day in a refrigerator.

**Determination of ALT** ALT (formerly glutamate pyruvate transaminase) catalyzes the equilibrium transfer reaction of the amino group from L-alanine to 2-oxoglutarate to form L-glutamate and pyruvate; ALT requires pyridoxal phosphate as coenzyme, which acts as an amino carrier. It is found in the main organs, such as the liver, kidney, and heart. The ALT activity in serum is elevated in diseases of the liver.

The spectrophotometric method for measurement of the ALT activity involves two reactions, a reaction catalyzed by ALT and an indicator reaction.

ALT catalyzes the reaction (reaction [VII]), and the pyruvate formed is reduced by NADH in a reaction catalyzed by LDH (indicator reaction, reaction [VIII]). The activity is measured by monitoring the decrease in absorbance of 340 nm due to the oxidation of NADH. The substrate concentrations are optimized theoretically, based on the kinetics of a two-substrate inhibited reaction because the ALT is subject to both substrate and product inhibitions.

The activity in serum samples decreases to 93% of the initial value after 3 days in a refrigerator.

**Determination of AMY** AMY catalyzes the hydrolysis of  $\alpha$ -1,4-glucan linkages to produce oligosaccharides. AMY is produced and stored in salivary glands and the pancreas and secreted into the digestive tract and eventually into the bloodstream. It is rapidly excreted into the urine because of its relatively small mass. Elevated levels of AMY activity in serum and urine are characteristics of acute pancreatitis or salivary lesions.

Many AMY reference methods based on malto-oligosaccharides with auxiliary enzymes and/or indicator enzymes have been recommended. For the direct method, an artificial substrate, 2-chloro-4-nitrophenyl- $\alpha$ -D-maltotriose (CNPT), is used for continuous monitoring of AMY activity. AMY hydrolyzes CNPT to maltotriose and 2-chloro-4-nitrophenol at high thiocyanate concentrations. The reaction is followed by monitoring the increase in absorbance due to the production of 2-chloro-4-nitrophenoxide at 405 nm. A side reaction (reaction [X]) occurs with formation of glucose and 2-chloro-4-nitrophenyl- $\alpha$ -D-maltose, which accounts for 8% of the product formed.

In the reaction,  $\text{Ca}^{2+}$  and  $\text{Cl}^-$  are required as activators.

The activity in a serum sample is stable for 5 days at room temperature.

## Determination of Enzyme Concentration

Determination of the concentration of all enzyme molecules, inactive as well as active, is essential in studying the clinical chemistry for diagnosis of disorders of metabolism because activity measurements alone are not sufficient for distinguishing whether the increase represents an increase in the number of all enzyme molecules present in sample; in some cases, inactive molecules are released from damaged tissues and a change in activity may not necessarily be directly related to the change in the number of molecules of enzyme present.

For determination of the enzyme concentration, methods of protein assay are frequently used; these are based on the general properties and behavior of proteins (nonspecific methods). For accurate determinations, the enzyme protein must be carefully purified because all methods are susceptible to

interferences from a large number of different enzymes and proteins that perhaps are present in physiological samples, and biological molecules, such as nucleic acids and amino acids.

Enzyme proteins have a number of general properties in common. However, of course, different enzyme proteins vary greatly in their amino acid composition and sequence as well as in their size, shape, and charge. Since the general properties and behavior of enzyme proteins are not always identical for different enzyme proteins, ideally a calibration curve should be constructed using the purified enzyme under study. In most cases bovine serum albumin is used as the standard or reference; therefore, enzyme protein quantities are obtained as 'serum albumin units' rather than as absolute amounts. Since different assay methods dependent on different general properties of enzymes, consistency between methods may be low. Furthermore, the various methods can hardly be expected to give equal responses with different enzymes; variability with different enzymes is large. Thus, no single method is optimal for every application.

### Enzyme Purification Methods

The body fluids and the extracts containing the enzyme will also contain numerous other substances. Small molecules in the sample can be easily removed through gel filtration and dialysis. The remaining large molecules are proteins and polysaccharides. The main part of purification consists of a series of fractionations by which the protein enzymes is separated from the other proteins present.

Although there are many fractionation methods, such as fractional precipitation using salts, organic solvents, or a change in pH, fractional denaturation by heating, and fractional adsorption, the purification of enzymes through chromatography on a column is the most effective of all the separation methods. The physicochemical properties of the enzyme that should be utilized in chromatography include the hydrophobicity, charge, biological recognition, and size. The mechanism of the separation depends in different cases on the adsorption, ion exchange, affinity to immobilized ligands, or molecular sieving, but the technique is practically the same for all.

Adsorption chromatography usually employs microcrystalline hydroxyapatite columns that adsorb proteins under conditions above pH 5. Gradient or step-wise elution with increasing concentration of eluting agent in the mobile phase may be used to release the enzyme required.

Hydrophobic chromatography of an enzyme employs cellulose derivatives with attached linear alkyl groups

$(-(CH_2)_n-CH_3, n = 1, 3, 5, 7, 9)$ , alkylamino groups  $(-(CH_2)_nNH_2, n = 2, 4, 6, 8, 10)$ , or the phenyl group.

In ion exchange chromatography cation exchangers, such as carboxymethyl cellulose, sulfoethyl cellulose, and sulfopropyl cellulose, are commonly used. The anion exchangers most commonly used are diethylaminoethyl cellulose and triethylaminoethyl cellulose.

Affinity chromatography involves the immobilization of a ligand (substrate, analog, inhibitor or effector) on agarose as a support that can be used selectively to adsorb the enzyme from a sample solution passed over it.

A mixture of enzymes can be separated by molecular size using the techniques of size exclusion chromatography. Packed bed columns of cross-linked dextran (Sephadex series), granulated polyacrylamide gels (Bio-Gel P series), or bead-formed agarose gels (Sephacrose series, Bio-Gel A series) which act as molecular sieves, are employed; enzyme proteins are eluted from the column in decreasing order of size, i.e., molecule weight.

In each technique, the eluate from the separation column is collected as a series of fractions by a fraction collector. The resulting enzyme solutions are concentrated to a smaller volume for the following determination. For the purpose of reduction in volume, ultrafiltration can be easily and rapidly performed; membranes with different porosities, which will retain the chosen macromolecule while being permeable to the solvent and to small molecules, are commercially available.

### Quantitation of Enzyme

**Nonspecific methods** Nonspecific methods for the determination of enzyme proteins are summarized in Table 1.

**Dry-weight analysis.** If a solution of highly pure enzyme is available, a dry-weight analysis may be possible. Though this should provide an exact value for the enzyme protein content, a great expense in labor and materials has to be devoted to the enzyme purification. Determination of the dry weight of a protein is important for investigations of protein structure.

**UV absorption method.** Most enzyme proteins absorb UV light at an absorption maximum at  $\sim 275\text{--}280\text{ nm}$  due to their content of tyrosine and tryptophan. If a pure enzyme is available, the absorbance at  $280\text{ nm}$  can be used for quantitation; for many enzyme proteins, a solution containing  $1\text{ mg}$  of protein per milliliter has an absorbance of  $1.0$  at  $280\text{ nm}$ . However, others differ in their absorbance with more than an order of magnitude due to the

**Table 1** Nonspecific methods for enzyme determination

<i>Method</i>	<i>Principle</i>	<i>Determination range</i>
Dry-weight method	Solution of the pure enzyme is evaporated to dryness and weight	> 0.1 µg
UV absorption method	Enzymes exhibit UV absorption maxima ~280 nm, based on their content of tyrosine and tryptophan residues. To increase the detectability, measurements at 215/225 nm are used because of the peptide bond	100–1000 µg ml <sup>-1</sup> (280 nm); 5–100 µg ml <sup>-1</sup> (215/225 nm)
Biuret method	Peptide bonds in a enzyme react with the Cu(II) ion in a strongly alkaline solution and produce a complex that can be determined spectrophotometrically at 540 or 310 nm	0.2–10 mg ml <sup>-1</sup> (540 nm); 30–500 µg ml <sup>-1</sup> (310 nm)
Bicinchoninic acid method	Bicinchoninic acid is added to the reaction products of the biuret reaction to form the copper–bicinchonate complex. The absorbance of the complex is measured spectrometrically at 560 nm	0.5–50 µg ml <sup>-1</sup>
Lowry method	The biuret reaction is incorporated with the reduction reaction of Folin-Ciocalteu's reagent and the resulting phosphomolybdenum blue is quantitated spectrophotometrically at 750 nm	2–100 µg ml <sup>-1</sup>
Protein–dye binding methods	Enzymes are stained with the dye Coomassie Brilliant Blue G-250 to produce color yields that exhibit absorption maxima at 595 nm	2–100 µg ml <sup>-1</sup>
Kjeldahl method	Ammonia produced by the oxidation of the enzyme by concentrated sulfuric acid is measured using the indophenol technique	0.5–10 µg ml <sup>-1</sup>
Fluorimetry	Amino groups in an enzyme derivatize with fluorescamine or <i>o</i> -phthalaldehyde, which is not fluorescent, and the resulting derivative is measured fluorimetrically	0.005–10 µg ml <sup>-1</sup>
Hydrolysis method	After alkaline hydrolysis, amino acids produced are reacted with ninhydrin or with <i>o</i> -phthalaldehyde and then measured spectrometrically or fluorimetrically	(ninhydrin) 20–500 µg ml <sup>-1</sup> ; ( <i>o</i> -phthalaldehyde) 10–1000 ng ml <sup>-1</sup>
Turbidimetry	Trichloroacetic acid is added to a solution of the enzyme to produce a suspension in the presence of a surface-active agent. The absorbance of the suspension is measured at 340 nm	5–120 µg ml <sup>-1</sup>
Refractometry	Refractive index change for the enzyme solution is measured using a differential refractometer	0.1–5 mg ml <sup>-1</sup>

different contents of the aromatic amino acids. Measurements at 280 nm can be used effectively only for monitoring proteins in effluents from chromatographic columns. To increase the detectability, measurement at below 220 nm is performed using shorter wavelength pairs, 215/225 nm; the absorption below 220 nm is based on the peptide bond ( $-\text{C}(=\text{O})-\text{NH}-$ ). UV absorption methods are non-destructive and can be easily and rapidly performed.

**Biuret method.** The biuret method is based on the reaction of peptide bonds with the copper(II) ion in

an alkaline solution leading to the formation of a violet colored complex. The variability with different proteins is smaller than that in the UV absorption method because the color development depends on the number of peptide bonds rather than the amino acid residues. The sensitivity of the biuret method is rather low. It appears that another method is more appropriate when better detectability is required. To improve the detectability, many modifications of the original procedure have been proposed that make use of the intense light absorption of copper complexes

with chromophores such as bicinchoninic acid (4,4'-dicarboxy-2,2'-biquinoline). The biuret method is practically suited for use as a reference method for determination of total enzyme protein owing its high precision.

**Lowry method.** The Lowry method is the most generally accepted owing to its sensitivity, simplicity, and reproducibility; it is  $\sim 20$  times more detectable than the UV absorption method and 100 times more sensitive than the biuret method. Since the color development in the Lowry method depends on the content of aromatic amino acid residues, the variation of response with different proteins is surely greater than in the biuret method but generally less than in UV adsorption measurement.

**Protein-dye binding method.** The protein-dye binding method is based on the shift in the absorption maximum of Coomassie Brilliant Blue G-250 from 465 to 595 nm that occurs upon binding of the dye to protein. The main disadvantage of this dye binding method is the variation of response with various proteins. The relative standard deviation in determinations of concentrations of 23 kinds of protein using the present method is about twice the value obtained using the Lowry method. Since bovine serum albumin gives a much higher color yield than most other proteins, the purified enzyme under study must be used as standard protein. If a sufficient quantity of the enzyme in purified form is not available in order to construct the calibration curve, bovine gamma globulin is recommended as a better standard that gives a more normal response.

**Kjeldahl method.** The Kjeldahl method is an important method for accurately determining nitrogen in proteins. Since a protein generally has a nitrogen content of  $\sim 16\%$  (12–19%), the quantity of protein can be calculated from a knowledge of the per cent nitrogen contained in it. Although, as mentioned above, rapid methods for determining proteins exist, the Kjeldahl method is the standard on which all other methods are based. The protein is digested with sulfuric acid to decompose it and convert the nitrogen to the ammonium ion, followed by spectrophotometric quantitation of the ammonium ion by reaction with hypochloride and phenol, forming indophenol blue.

**Other methods.** Other methods of high detectability (determination range  $0.005\text{--}10\ \mu\text{g ml}^{-1}$ ) include fluorimetric techniques such as binding fluorescamine, o-phthalaldehyde, dansyl chloride, 4-fluoro-7-nitrobenzo-2-oxa-1,3-diazole, 1-anilinonaphthalene-8-sulfonic acid, and hypochlorite-thiamine. Estimation of protein using ninhydrin ( $20\text{--}500\ \mu\text{g ml}^{-1}$ ) or o-phthalaldehyde ( $10\text{--}1000\ \text{ng ml}^{-1}$ ) after alkaline hydrolysis, turbidimetry ( $5\text{--}12\ \mu\text{g ml}^{-1}$ ), or refractometry ( $0.1\text{--}5\ \text{mg ml}^{-1}$ ) has been proposed.

**Specific methods** Immunochemical methods have been developed for identification and specific determination of proteins that have no catalytic activity. The method is based on the special relationship between a protein and a specific antibody that has been raised against the protein. The advantages of an immunoassay lie in its high specificity and detectability. Since the specificity is independent of the activity of the antigen protein, the method measures all enzyme molecules, inactive as well as active. The methods depend on the availability of specific antisera directed against the particular enzymes under study. The antibody is raised in an experimental animal by injection of a sample of protein antigen. Selective precipitation method and enzyme linked immunosorbent assay (ELISA) are commonly used for the specific detection and reliable measurement of a particular enzyme in a raw sample, such as a tissue extract or body fluids.

**Selective precipitation methods.** The principle of the selective precipitation method is that excess antibody is added to a solution of enzyme to precipitate it as an insoluble antigen-antibody complex. The precipitate may be separated and analyzed for its enzyme content. This method permits the specific measurement of several nanograms of enzyme protein.

**ELISA** ELISA is based on the principle of competition between enzyme-labeled and unlabeled antigens for a specific antibody present in a limited concentration in the assay mixture. The labeled antigen and antibody form a reversible complex. The complex is then detectable by assay of the linked enzyme. Since a pure sample of antigen is required for preparation of standards, the method has not been applied extensively to the determination of enzyme concentrations.

### Introduction

The world enzyme market is currently valued in the region of US\$1.3 billion and is made up of markets such as detergents (37%), textiles (12%), starch (11%), baking (8%), and animal feed (6%).

There has been much recent corporate investment in the field of biocatalysis with leading fine chemical companies now beginning to supplement traditional chemical and metal catalysis with biocatalysis. This will lead to more and more practical industrial uses

of enzymes in the twenty-first century. A comprehensive review of present industrial processes using enzymes can be found in the book *Industrial Enzymology*.

The pharmaceutical industry is driven primarily by the need for innovative medicines with new vaccines occupying only a small area of the market compared to small molecule products for oral ingestion. The variable activity of different optical isomers and regulatory pressures has led to the desire to manufacture only chirally pure therapeutics. Thus, biocatalysis with its high selectivity offers great opportunities. The top two drugs in terms of global sales – Lipitor (Pfizer) and Zocor (Merck), with combined sales of almost \$14 billion in 2002 – are single-enantiomer small-molecule drugs. Worldwide sales of single-enantiomer drugs have now reached more than \$159 billion.

### Introduction

The world enzyme market is currently valued in the region of US\$1.3 billion and is made up of markets such as detergents (37%), textiles (12%), starch (11%), baking (8%), and animal feed (6%).

There has been much recent corporate investment in the field of biocatalysis with leading fine chemical companies now beginning to supplement traditional chemical and metal catalysis with biocatalysis. This will lead to more and more practical industrial uses

of enzymes in the twenty-first century. A comprehensive review of present industrial processes using enzymes can be found in the book *Industrial Enzymology*.

The pharmaceutical industry is driven primarily by the need for innovative medicines with new vaccines occupying only a small area of the market compared to small molecule products for oral ingestion. The variable activity of different optical isomers and regulatory pressures has led to the desire to manufacture only chirally pure therapeutics. Thus, biocatalysis with its high selectivity offers great opportunities. The top two drugs in terms of global sales – Lipitor (Pfizer) and Zocor (Merck), with combined sales of almost \$14 billion in 2002 – are single-enantiomer small-molecule drugs. Worldwide sales of single-enantiomer drugs have now reached more than \$159 billion.

## Application of Enzymes in the Detergent, Textile, Leather, Paper, Animal Feed, Baking, and Alcohol Industries

The detergent industry saw the first large-scale use of microbial enzymes, namely, proteinases. However, in the late 1980s lipases were introduced to break down fats into water-soluble components of glycerol and fatty acids. Amylases remove starch-based stains, and since the early 1990s cellulases have been used to remove cotton-based cellulose. The textile industry is rapidly increasing its dependence on enzymology where amylases now strip the fabrics' protective coating of starch whilst cellulases provide the 'worn look' denim. The other industries also use hydrolytic enzymes to manufacture their products (see Table 1).

### Determination of $\alpha$ - and $\beta$ -Amylase

Amylases are responsible for hydrolysis of starch to oligosaccharides.  $\alpha$ -Amylase hydrolyzes the 1,4- $\alpha$ -glucoside bonds in compounds involving three or more molecules of glucose.  $\beta$ -Amylase liberates (mainly)  $\beta$ -maltose from starch and other compounds. The simplest way to determine amylase activity requires the determination of the time required to change the starch iodine color from blue

to reddish brown. This time is proportional to the amylase activity.

Two different kinetic methods are available for the determination of amylase activity used in clinical diagnostics. These methods can be applied for the analysis of industrial products.

The reactions involved in the first method are

where NADH is the abbreviation for (reduced) nicotinamide adenine dinucleotide.

The rate of increase in absorbance at 340 nm due to the formation of NADH is directly proportional to

**Table 1** Applications of enzymes in the detergent, textile, leather, paper and pulp, and alcohol industries

Enzyme	Substrate	Industry	Source
$\alpha$ - and $\beta$ -Amylases	Starch	Detergent, textile, alcohol, paper, and pulp	<i>Bacillus amyloliquefaciens</i>
		Baking	<i>Bacillus licheniformis</i> <i>Bacillus polymyxa</i> <i>Aspergillus oryzae</i>
Amyloglucosidase	Dextrins	Alcohol	<i>Aspergillus niger</i>
		Baking	<i>Rhizopus nivens</i> <i>Aspergillus niger</i>
Cellulases (alkaline, neutral, and acidic)	Cellulose	Detergent, textile	<i>Phanerochaete chrysosporium</i> <i>Trichoderma reesei</i> <i>Bacillus</i> spp., <i>Trichoderma longibrachiatum</i>
Lipases	Lipids	Detergent	<i>Candida ruqusa</i>
		Baking	<i>Geotrichum parasitica</i> <i>Aspergillus oryzae</i>
Proteinases (alkaline, neutral, and pepsin- or rennin-like)	Proteins	Detergent, textile, alcohol, leather	<i>Aspergillus oryzae</i>
		Baking	<i>Endothia parasitica</i> <i>Bacillus subtilis</i>
Xylanases	Xylan	Animal feed, baking, paper, and pulp	<i>Trichoderma longibrachiatum</i>

amylase activity. Multienzyme preparations catalyzing these reactions are commercially available.

The reactions involved in the second method are

The increase in absorbance at 405 nm is proportional to the amylase activity. It might be pointed out that many different assay procedures and 'units of amylase activity' are used in the literature.

#### Determination of Amyloglucosidase

Amyloglucosidase removes consecutive glucose molecules from starch and some other compounds. Reactions [VI] and [VII] are also suitable for detection of amyloglucosidase activity. The best method is generally to determine the rate of glucose formation.

There are many different experimental procedures for glucose detection. One nonenzymatic and two enzymatic methods for glucose detection are described below.

The nonenzymatic method for glucose detection involves reaction [VIII] carried out in a boiling water bath:

The absorbance, measured spectrophotometrically at 620–650 nm, is directly proportional to the glucose concentration.

The first enzymatic method for glucose detection involves the reactions

The absorbance of the brown product, measured at 425–475 nm, is proportional to the total glucose concentration.

The second enzymatic method for glucose detection makes use of reactions [XI] and [XII]:

The absorbance at 340 nm due to the formation of NADH is proportional to the glucose concentration.

One unit of amyloglucosidase activity is defined as the amount of enzyme that releases 1 mg of glucose from starch in 1 min at pH 4.5 and 55°C.

#### Determination of Cellulase

Cellulase catalyzes the hydrolysis of 1,4- $\beta$ -glucosidic bonds in cellulose, lichenin, and other polysaccharides. One unit of cellulase activity releases 1  $\mu\text{mol}$  of glucose from cellulose in 1 h at pH 5.0 and 37°C. Useful methods for determining the rate of glucose formation are described above, and may be employed for cellulase determination.

#### Determination of Lipase

Lipase liberates fatty acids from triglycerides. The rate of fatty acids formation is measured by titration with standard sodium hydroxide solution. Microcalorimetric methods can also be used; the enzyme is determined by the heat generated in the reaction in Tris buffer at pH 8.0. One unit of lipase activity liberates 1 microequivalent of fatty acid from a triglyceride in 1 h at pH 7.7 and 37°C.

#### Determination of Proteinases (Proteases)

Proteinases catalyze the hydrolysis of peptide bonds in proteins. The selectivity of action of some proteinases is shown in Figure 1.

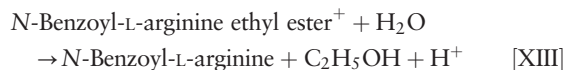

Pepsin, pepsin-like enzymes, chymosin, rennin, and other acid proteinases have an activity optimum at pH 2.0–3.5; papain, trypsin, chymotrypsin, and similar enzymes are most active at neutral pH (pH 6–8). Subtilisin BPN, pancreatic elastase, leucine

**Figure 1** Scheme showing the selectivity of action of three proteinases: trypsin,  $R_1 = \text{Lys, Arg}$ ; chymotrypsin,  $R_1 = \text{Phe, Trp, Tyr}$ ; and pepsin,  $R_2 = \text{Phe, Trp, Tyr, Leu, Asp, Glu}$ .

aminopeptidase (cytosol), and other alkaline proteinases work best at pH > 8.

Many proteinases cleave not only peptide bonds but also ester bonds. Determinations of trypsin, chymotrypsin, papain, and some other enzymes are based on this property. The standard substrate for activity determination of trypsin and papain is *N*-benzoyl-L-arginine ethyl ester (BAEE), and for chymotrypsin, *N*-benzoyl-L-tyrosine ethyl ester. For example:

The reaction may be monitored by spectrophotometry or microcalorimetry.

Some proteinases use high relative molecular mass substrates as standards. For example, hemoglobin is a standard substrate for pepsin, angiotensinogen is a substrate for renin, elastin for elastase, and casein for chymosin.

### Determination of Xylanase

Soluble oat spelt xylan is used as the substrate for xylanase activity. The assay is carried out for 30 min at 40°C in 100 ml potassium phosphate buffer at pH 6.0. The release of reducing sugar from the breakdown of xylan is measured using the dinitrosalicylic (DNS) reagent method. After the addition of DNS reagent, each assay should be covered and placed in a bath of boiling water for exactly 5 min, followed by rapid cooling in cold water to room temperature. The absorbance of each tube should then be determined relative to the blank at 540 nm. One unit (U) of xylanase activity is defined as the amount of enzyme that produces reducing sugars corresponding to 1 μmol of xylose per minute.

## Enzyme Determination in Pharmaceutical Products

The enzymes that are successfully applied in pharmaceuticals are shown in Table 2. Those enzymes catalyzing the conversion of low relative molecular mass substrates will be considered first. They are asparaginase, rhodanese, uricase, and trypsin. These enzymes (except for trypsin) are used to carry out the conversion of lower relative molecular mass substrates not only under laboratory conditions, but also in living systems.

The reaction catalyzed by asparaginase (glutaminase) is shown in Table 2. The ammonia released is used to monitor enzyme activity. It can be detected spectrophotometrically by the classical color analytical reaction with phenol and sodium hypochlorite, or

by using L-glutamate dehydrogenase:

Alternatively, the small differences in ultraviolet spectra of asparagine and aspartate may also be used for developing a spectrophotometric method of detection.

In the case of rhodanese, the rate of thiocyanate ( $\text{SCN}^-$ ) formation should be measured by usual chromogenic reactions for thiocyanate ions.

Hydrogen peroxide is one of the products of the reaction catalyzed by uricase. It may be detected spectrophotometrically by reaction with some dyes, e.g., *o*-dianisidine, or 4-aminoantipyrine + *p*-hydroxybenzene sulfonate, and the enzyme peroxidase. The reaction with *o*-dianisidine has been described above.

High relative molecular mass substrates are the standards for collagenase, hyaluronidase, lysozyme, ribonuclease, streptokinase, and urokinase. It should be emphasized that small variations in the quality of 'high relative molecular mass standards' or conditions can result in sharp changes in the apparent composition of reaction products and can lead to nonreproducible results.

Simple, low relative molecular mass substrates are needed for detecting enzyme activity to obtain reproducible results. For example, the method for collagenase activity determination using furylacryloyl-Leu-Gly-Pro-Ala (FALGPA) is preferable to the method using collagen as a substrate. First, low relative molecular mass substrates are more selective with respect to different enzymes (e.g., FALGPA, unlike collagen, is not hydrolyzed by nonspecific proteases, which often exist in collagenase preparations). Second, the value of the enzyme activity measured by low relative molecular mass standards has an exact chemical meaning (e.g., the activity in hydrolyzing the Leu-Gly bond in FALGPA or in 4-phenylazobenzyloxycarbonyl-Pro-Leu-Gly-Pro-D-Arg).

The application of low relative molecular mass substrates (e.g., for trypsin) allows the assignment of enzyme activity values not only in the units of absorbance change at 253 nm ( $\Delta A_{253}$ , see Table 2), but also in the units micromoles of substrate per minute (hydrolysis of a particular bond); this second value can also be obtained from microcalorimetric determination.

This should not be interpreted as a call for the immediate rejection of high relative molecular mass substrates for enzyme activity determination. In all likelihood, two types of standards (low and high relative molecular masses) may be widely used in the near future. However, it is likely that the low relative

**Table 2** Application of enzymes as therapeutic agents

Enzyme	Reaction catalyzed	Therapeutic application	Method for detection of activity	Definition of activity unit <sup>a</sup>
Asparaginase (glutaminase)	$\text{L-Asparagine}^{+ -} (\text{L-glutamine}^{+ -}) + \text{H}_2\text{O} \rightarrow \text{L-aspartate}^{-} (\text{L-glutamate}^{-}) + \text{NH}_4^{+}$	Leukemia	Spectrophotometry, potentiometry (ammonia-selective electrode), or microcalorimetry	One unit liberates 1.0 $\mu\text{mol}$ of ammonia from L-asparagine (or L-glutamine) per min at pH 8.6 and 37°C
Collagenase	Hydrolysis of peptide bonds in spiral portions of collagen molecules	Skin ulcers	Spectrophotometry	<i>Chromatographically pure</i> : one unit liberates peptides from collagen equivalent in ninhydrin color to 1.0 $\mu\text{mol}$ of leucine in 5 h at pH 7.4 and 37°C in the presence of calcium ions <i>Crude; nonspecific proteases and clostripain-containing</i> : one unit hydrolyzes 1.0 $\mu\text{mol}$ of furylacryloyl-Leu-Gly-Pro-Ala per min at 25°C at pH 7.5 in the presence of calcium ions. This substrate is specific for collagenase and is not hydrolyzed by proteases
Hyaluronidase	Hydrolysis of 1,4 bonds between 2-acetamido-2-deoxy- $\beta$ -D-glucose and D-glucuronic acid in hyaluronic acid. Enzyme also hydrolyzes 1,4-bonds in some other polysaccharides containing sulfate groups	Heart attack	Spectrophotometry	One unit produces absorbance equivalent to 1.0 $\mu\text{g}$ of glucuronic acid per hour from hyaluronic acid, using 3,5-dinitrosalicylic acid to develop the color.
Lysozyme	Cell-wall hydrolysis of some bacteria. Hydrolysis of 1,4 bonds between 2-acetamido-2-deoxy- $\beta$ -D-glucose and N-acetylmuramic acid	Antibiotic	Spectrophotometry	One unit produces a change in absorbance at 450 nm of 0.001 per min at pH 6.2 and 25°C, using a suspension of <i>Micrococcus lysodeikticus</i> as substrate, in a 2.6 ml reaction volume (1 cm light path)
Rhodanese	$\text{S}_2\text{O}_3^{2-} + \text{CN}^{-} \rightarrow \text{SO}_3^{2-} + \text{SCN}^{-}$	Cyanide poisoning	Spectrophotometry	One unit converts 1.0 $\mu\text{mol}$ of cyanide to thiocyanate per min at pH 8.6 and 25°C
Ribonuclease	Hydrolysis of pyrophosphate bonds in ribonucleic acids	Antiviral	Spectrophotometry	One unit produces soluble oligonucleotides equivalent to a change in absorbance at 260 nm of 1.0 in 30 min at pH 7.5 and 37°C in a 1.5 ml reaction volume
Streptokinase + urokinase	Conversion plasminogen to plasmin	Blood clots	Spectrophotometry	<i>Streptokinase</i> : one unit will liquefy a standard clot of fibrinogen, plasminogen, and thrombin at pH 7.5 and 37°C in 10 min <i>Urokinase</i> : one unit activates the amount of plasminogen which produces a change of absorbance of 1.0 per ml per min at pH 7.5 and 37°C when measuring perchloric acid-soluble products from $\alpha$ -casein (1 cm light path)
Trypsin	Protein hydrolysis (for details see industrial section above)	Inflammation	Spectrophotometry or microcalorimetry	One BAEE ( <i>N</i> -benzoyl-L-arginine ethyl ester) unit is an absorbance change at 253 nm of 0.001 per min with BAEE as substrate at pH 7.6 and 25°C
Urease	$\text{Uric acid} + 2\text{H}_2\text{O} + \text{O}_2 \rightarrow \text{Allantoin} + \text{CO}_2 + \text{H}_2\text{O}_2$	Gout	Spectrophotometry	One unit converts 1.0 $\mu\text{mol}$ of uric acid to allantoin per min at pH 8.5 and 25°C

## Enzyme-Based Assays

**K Matsumoto**, Kyushu University, Fukuoka, Japan

**H Ukeda**, Kochi University, Nankoku, Japan

© 2005, Elsevier Ltd. All Rights Reserved.

## Principle

Enzymatic analysis involves the determination of sample constituents, which can be both substrates and inhibitors of enzymes, and the determination of enzyme activity occurring in the sample. Such analyses are carried out on a wide variety of materials, particularly foodstuffs and their precursor raw materials.

Figure 1 illustrates the dependence of an enzyme-catalyzed reaction rate on the substrate concentration. An enzyme is characterized by the number of molecules of substrate that it can convert to the product; that is, turnover number. As long as the substrate concentration is small enough with respect to the enzyme concentration that the turnover number is not exceeded, the reaction rate is directly proportional to the substrate concentration; that is, it is first order with respect to substrate. If the enzyme concentration is held constant, then the overall

reaction is first order and directly proportional to substrate concentration. This serves as the basis for substrate determination.

When the amount of substrate exceeds the turnover number corresponding to the amount of the enzyme present, the enzyme becomes saturated with respect to the number of molecules that it can complex and the reaction rate reaches a maximum value. If the enzyme is saturated with respect to substrate, then the overall reaction is first order with respect to enzyme concentration. Since a linear relationship between reaction rate and enzyme activity will exist, this becomes the basis for enzyme determination.

## Enzyme Activity Determination

In the determination of the substrate concentration, the accuracy of the results obtained by a method can be checked by comparison with a weighed-in standard. In contrast, the accuracy of the determination of the catalytic activities of enzymes can be achieved only on the basis of defined conditions of measurement. The weighing in of a crystalline enzyme with a definite catalytic activity would by no means lead to identical, accurate results under different conditions of measurement. The measurement conditions refer to the temperature, the type of the buffer, its concentration, the pH, co-factors, activators, substrate(s), and their concentration(s). For example, the temperature coefficient of the reaction rate can be as large as 10% per degree centigrade or more. This means that for a temperature rise of 1°C, the value found for the catalytic activity of an enzyme is ~10% higher. The substrate should be in excess so that the reaction rate depends only on the enzyme concentration. In order to achieve a value of  $0.99V_{\max}$  (99% of a maximum reaction rate),  $99K_m$  (99-fold substrate concentration

**Figure 1** Dependence of enzyme-catalyzed reaction rate on substrate concentration.

molecular mass standards will be more useful in the future.

© 2005, Elsevier Ltd. All Rights Reserved.

## Principle

Enzymatic analysis involves the determination of sample constituents, which can be both substrates and inhibitors of enzymes, and the determination of enzyme activity occurring in the sample. Such analyses are carried out on a wide variety of materials, particularly foodstuffs and their precursor raw materials.

Figure 1 illustrates the dependence of an enzyme-catalyzed reaction rate on the substrate concentration. An enzyme is characterized by the number of molecules of substrate that it can convert to the product; that is, turnover number. As long as the substrate concentration is small enough with respect to the enzyme concentration that the turnover number is not exceeded, the reaction rate is directly proportional to the substrate concentration; that is, it is first order with respect to substrate. If the enzyme concentration is held constant, then the overall

reaction is first order and directly proportional to substrate concentration. This serves as the basis for substrate determination.

When the amount of substrate exceeds the turnover number corresponding to the amount of the enzyme present, the enzyme becomes saturated with respect to the number of molecules that it can complex and the reaction rate reaches a maximum value. If the enzyme is saturated with respect to substrate, then the overall reaction is first order with respect to enzyme concentration. Since a linear relationship between reaction rate and enzyme activity will exist, this becomes the basis for enzyme determination.

## Enzyme Activity Determination

In the determination of the substrate concentration, the accuracy of the results obtained by a method can be checked by comparison with a weighed-in standard. In contrast, the accuracy of the determination of the catalytic activities of enzymes can be achieved only on the basis of defined conditions of measurement. The weighing in of a crystalline enzyme with a definite catalytic activity would by no means lead to identical, accurate results under different conditions of measurement. The measurement conditions refer to the temperature, the type of the buffer, its concentration, the pH, co-factors, activators, substrate(s), and their concentration(s). For example, the temperature coefficient of the reaction rate can be as large as 10% per degree centigrade or more. This means that for a temperature rise of 1°C, the value found for the catalytic activity of an enzyme is ~10% higher. The substrate should be in excess so that the reaction rate depends only on the enzyme concentration. In order to achieve a value of  $0.99V_{\max}$  (99% of a maximum reaction rate),  $99K_m$  (99-fold substrate concentration

**Figure 1** Dependence of enzyme-catalyzed reaction rate on substrate concentration.

of Michaelis constant) is required theoretically. Similarly, for 98, 97, 96, and 95% of  $V_{\max}$ , the substrate concentrations can be calculated as  $49K_m$ ,  $32.3K_m$ ,  $24K_m$ , and  $19K_m$ , respectively. The optimum substrate concentration is practically selected by technical conditions (solubility of the substrate, absorption of light, and so on) or the properties of the enzyme (inhibition by substrates or products).

Spectrophotometric methods are most widely employed to monitor enzyme reactions. The reaction product may have an absorption spectrum different from the substrate, allowing simple measurement of the product or substrate. The typical example is the determination of dehydrogenase activity. The co-enzyme of dehydrogenases, nicotinamide adenine dinucleotide, exhibits marked differences in ultraviolet absorption spectrum between the reduced (NADH) and oxidized ( $\text{NAD}^+$ ) forms (Figure 2).  $\text{NAD}^+$  has a negligible absorption at 340 nm, while NADH has a characteristic absorption maximum. Thus, the absorption is widely used for following the dehydrogenase reactions. The example is the determination of the enzyme lactate dehydrogenase (LDH).  $\text{NAD}^+$  is required in the LDH-catalyzed oxidation of lactic acid to pyruvic acid:

The reaction is reversible and can be employed in either direction. In the forward reaction, a sample containing an unknown amount of LDH would be added to a solution containing lactic acid and  $\text{NAD}^+$  at the enzyme saturating concentrations, and the increase in absorbance at 340 nm would be measured as a function of time.

This convenient spectrophotometric property of NADH can be useful for monitoring enzyme reactions in which it is not directly involved by using it as

a coupling agent in a secondary reaction with the product. For example, glutamate-oxalate transaminase (GOT) catalyzes the reaction of  $\alpha$ -ketoglutarate and aspartate to glutamate and oxaloacetate and the product is reduced by NADH in the presence of another enzyme, malate dehydrogenase (MDH):

The second reaction should be fast compared to the first in the presence of an excess of MDH, and so the rate of decrease in NADH concentration is directly proportional to the GOT activity.

## Substrate Determination

Two general techniques, endpoint method and kinetic method, can be used for measuring substrates. The endpoint method utilizes the completion conversion of the substrate. Before and following completion of the enzymatically catalyzed reaction, a product is analyzed or the depletion of a reactant that was originally in excess is measured. The analyzed substrate (net change) is then related to the original substrate concentration. These reactions are often not stoichiometric with respect to the substrate concentration because of possible side reactions or instability of products or reactants. Also, the reaction may require extraordinarily long times for completion. For these reasons, the analytical procedure is usually standardized by preparing a calibration curve of some type in which the measured quantity is related to known concentrations or quantities of the substrate.

The kinetic method employed for substrate determination is the measurement of the rate of an enzymatically catalyzed reaction, as is used to determine enzyme activity. Rate methods are generally more rapid than the endpoint method. Complete conversion reactions, on the other hand, are less subject to interference from enzyme inhibitors or activators as long as sufficient time is allowed for completion conversion.

## Endpoint Method

### One-Step Reaction

A substrate S is to be determined. S shall be completely converted into the product P in an enzymatic reaction. If S has a characteristic light absorption in the ultraviolet or visible range different from P, S can be directly determined even in the

**Figure 2** Absorbance of NAD and NADH as a function of wavelength. NADP and NADPH show nearly the same curves.

presence of other absorbing substances in the spectrophotometer cuvette. The absorbance decreases by an amount corresponding to the quantity of S converted. Various measuring techniques can be used as well as absorption photometry, such as fluorimetry, luminometry, calorimetry, and potentiometry. If dissolved oxygen is consumed by the reaction, especially such as oxidase reaction, the oxygen consumed is monitored by a Clark-type oxygen electrode amperometrically. This measuring technique is advantageous for colored or turbid sample solution.

The most widely used enzymatic reactions are those with NAD(P)-dependent dehydrogenases. By monitoring the absorbance at 340 nm, the enzymatic conversion of the substrate can be followed directly in the photometer cuvette without influencing the chemical process. The substrate concentration can be calculated using the molar extinction ( $\epsilon_{340} = 6.3 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$ ) of NADH.

All enzymatic reactions involving co-enzymes are two-step reactions. However, if one of the substrates is present in a very high concentration in relation to its Michaelis constant, two-substrate reactions can be treated kinetically as one-substrate reactions. These conditions are also desirable for endpoint determinations with co-enzymes, simply to achieve a high reaction rate. However, if NAD(P)H is the second substrate, the degree to which its concentration can be increased is limited by its high absorbance. On the basis of experience, relatively large quantities of enzyme are used with relatively little substrate, so that the reaction proceeds rapidly to completion. The absorbance should thus be easily readable (neither too low nor too high).

Generally, enzyme reactions are equilibrium reactions. If the conversion is incomplete because of an unfavorable equilibrium, a determination is only possible with shifting the equilibrium by special experimental techniques. The equilibrium can be shifted by the increase of substrate concentration, variation of pH, and by trapping agents. The equilibrium constant may be altered by several orders of magnitude. The use of trapping agents, for example, semicarbazide and hydrazine when ketones and aldehydes are reaction product, is convenient for achieving the purpose. However, this technique is not always useful. Trapping agents can inhibit the catalyzing enzyme, as in the case of 3-hydroxybutyrate dehydrogenase (EC 1.1.1.30). Semicarbazide and hydrazine react slowly with NAD to form a compound that absorbs in the longwave ultraviolet and overlaps the absorption spectrum of NADH. The more elegant way is to use a trapping enzyme reaction, whose equilibrium is far

in favor of the reaction products. Total substrate conversion can be achieved by coupling such a trapping reaction with the primary reaction. Moreover, if the trapping reaction itself is catalyzed by an NAD(P)-dependent enzyme, in many cases the measuring signal is doubled, as in the case of the determination of ethanol using alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (AIDH):

The equilibrium of the alcohol dehydrogenase reaction is far in favor of ethanol; however, ethanol conversion can be completed by continuous oxidation of acetaldehyde dehydrogenase reaction.

### Coupled Reaction

In some enzyme reactions, none of the reactants or products can be readily monitored by physical and chemical measurements. In such cases, it is often possible to determine one of these components enzymatically. This considerably increases the number of substances that can be determined by these methods.

The reaction in which the substance to be determined is transformed is known as the auxiliary, while the reaction used for the actual measurement is called the indicator reaction. Both reactions can generally be carried out in a single assay mixture (coupled reactions). If a product of the auxiliary reaction is measured in the indicator reaction, one speaks of a succeeding indicator reaction. In this case, the function of the auxiliary enzyme is to convert the substance to be analyzed into a substance that can be measured in the indicator reaction. An example is the determination of glucose using hexokinase (HK) and glucose-6-phosphate dehydrogenase (G6P-DH).

Auxiliary reaction:

Indicator reaction:

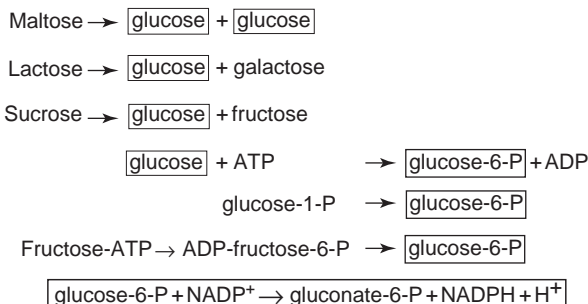

In the auxiliary reaction, glucose is phosphorylated by ATP to glucose-6-phosphate (glucose-6-P), which is the substrate of the NADP-dependent indicator reaction.

Several auxiliary reactions may also be carried out in succession, for example, in the sequence

If different auxiliary reactions give rise to the same reaction product such as the analysis of sugars, only one indicator reaction is required:

These reactions finally yield glucose or glucose-6-phosphate, and therefore all of these compounds can be determined by the glucose-6-phosphate dehydrogenase as indicator reaction. These assay methods have attracted much interest in the analysis of foods.

## Kinetic Method

The second technique employed for substrate determination is the measurement of the rate of an enzymatically catalyzed reaction, as is used to determine enzyme activity. The kinetic assay may be successfully used for determination of substances that do not react in a manner that can be detected directly, or in cases where the quantity of the substrate is too low to measure with the simple endpoint method. The determination of substrate using kinetic methods is possible only when the substrate concentration is low enough compared with the Michaelis constant. Thus, the following is required to perform the assay:

1. For a two-substrate reaction, the concentration of the second reactant must be so high that the rate of reaction depends only on the concentration of the substrate that is being analyzed.
2. Enzymes with high Michaelis constants are required; this enables relatively high substrate concentrations to be determined.
3. If enzymes with high Michaelis constants are not available, the apparent  $K_m$  is increased by using competitive inhibitors.

Typical examples of the kinetic determination are the determination of glucose with the use of pseudo-first-order reactions. Glucose can be determined by

glucose oxidase and Trinder's color reagent according to the following reaction scheme:

Glucose oxidase oxidizes only the  $\beta$ -form of glucose. However, this kinetic method permits the determination of the total amount of glucose present in the solution as a mixture of isomers. The  $\alpha$ - and  $\beta$ -forms of glucose undergo spontaneous interconversion by mutarotation. By choosing appropriate conditions of measurement, one can ensure that the rate of the overall reaction will be determined first by the conversion of the  $\beta$ -form already present in the solution by glucose oxidase, and then by the subsequent production of the  $\beta$ -form by mutarotation of  $\alpha$ -form. Since the Michaelis constant of glucose oxidase, with a value of  $7 \times 10^{-2} \text{ mol l}^{-1}$ , is always substantially greater than the glucose concentrations encountered in assay mixture in practice ( $\sim 8 \times 10^{-6}$  to  $5 \times 10^{-4} \text{ mol l}^{-1}$ ), the oxidation of glucose by glucose oxidase obeys pseudo-first-order kinetics with respect to  $\beta$ -glucose. The kinetics of mutarotation is of the same order. This is because here only the concentration of the glucose isomer changes, while the concentration of water as reactant remains practically constant. This results in a sequence of coupled reactions that are pseudo-first-order in glucose concentration, and to which one can therefore apply the principle of the kinetic 'fixed-time' measurement to determine the glucose concentration. The parameter measured in this method is the change in the absorbance of the dye formed during a fixed time interval.

## Activator and Inhibitor Determinations

Enzymes are involved in many of the chemical reactions that take place in biological processes. Enzymes generally have high specificity for a given substrate and do not attack closely related substrate molecules. This selectivity of enzyme and their ability to catalyze reactions of substrate at low concentrations are of great use in chemical analysis. The activities of enzymes were influenced by many kinds of factors, for instance, pH, temperature, ionic strength, activators, and inhibitors. By use of activity changes of enzymes between the presence and absence of activator (or inhibitor), one can determine the concentration of the activator (or inhibitor). An

activator is either a substance that is required for an enzyme to be active, i.e., it converts the inactive apoenzyme to the active holoenzyme, or one that increases the efficiency of an active enzyme. An inhibitor is a substance that decreases the reaction rate, either by reacting with the enzyme to form a complex or by reacting with one of the substrates.

There are two main inhibition types that one can use for inhibitor determinations, competitive and noncompetitive inhibitions. In case of competitive inhibition, inhibitors structurally related to the substrate may be bound to the enzyme active center and compete with the substrate. Because the formation of the complex between the enzyme and the inhibitor is a reversible reaction, the inhibitor can be displaced by a high concentration of the normal substrate. In the case of noncompetitive inhibition, the inhibitor combines with the enzyme at a site that is often different from the substrate binding site, and as a result inhibits the formation of the product by the breakdown of the normal enzyme–substrate complex. It is generally not reversed by the addition of excess substrate.

Competitive and noncompetitive inhibitions change enzyme kinetics differently. A competitive inhibitor does not change  $V_{\max}$  (maximum velocity) but increases  $K_m$ ; a noncompetitive inhibitor decreases  $V_{\max}$  and  $K_m$  remains unchanged.

Because enzymes are catalysts, which affect the rate and does not affect the equilibrium or endpoint of a reaction, their concentration and activity must be measured by a kinetic method. In such a kinetic method it is not necessary to wait for equilibrium to be established.

### Assay of Activators

The effect of activator concentration on the initial rate of an enzyme reaction is similar to that of substrate concentration. At low concentrations of activator there is a first-order dependence of the rate on activator concentration. At higher concentrations the enzyme is maximally activated and the rate is independent of activator concentration. Consequently, lower concentration is preferred for assay of activators. The basic technique for determination of metal ions is the use of metalloenzymes converted to apoenzymes, the latter being reconverted to the holoenzymes by binding with the metal ions. In this case, the metal ion in the holoenzyme is first removed by adding a chelating agent such as ethylenediaminetetraacetic acid. For instance, one can determine  $\text{Ca}^{2+}$  or  $\text{Zn}^{2+}$  by use of apoalkaline phosphatase and  $\text{Co}^{2+}$  or  $\text{Cu}^{2+}$  by use of apoaminopeptidase. Many researchers have reported the activation of

isocitrate dehydrogenase by metal ions, such as  $\text{Mn}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{Zn}^{2+}$ :

- $\text{Ca}^{2+}$  and  $\text{K}^{+}$ :  $\text{Ca}^{2+}$  activates a number of enzyme systems: pancreatic lipase is activated by  $\text{Ca}^{2+}$  in the presence of bile and insoluble triglycerides, and bacterial 2-oxyglutarate dehydrogenase is also activated by  $\text{Ca}^{2+}$ . The apoenzyme of calf intestinal alkaline phosphatase is activated by  $\text{Ca}^{2+}$ .  $\text{K}^{+}$  activates phosphate fructokinase and pyruvate kinase, respectively.
- $\text{Mg}^{2+}$  and  $\text{Mn}^{2+}$ : Isocitrate dehydrogenase (ICDH) is activated by  $\text{Mg}^{2+}$ . The rate of the ICDH reaction is proportional to magnesium under the condition of constant amounts of ICDH and nonrate-limiting concentration of isocitrate and NADP. The formation of NADPH ( $\lambda_{\max} = 340 \text{ nm}$ ) can be monitored spectrophotometrically. Both  $\text{Mg}^{2+}$  and  $\text{Mn}^{2+}$  can activate heart pyruvate dehydrogenase and bacterial 2-oxyglutarate dehydrogenase, and can be determined.
- $\text{Zn}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Ni}^{2+}$ : Apoaminopeptidase was prepared by removing zinc from pig kidney amino peptidase, a commercially available metalloenzyme. By use of this apoamino peptidase, one can determine zinc concentration up to a given limit, giving the enzyme activity of the apoenzyme being strictly proportional to the concentration of zinc ions in the assay system. The analytical procedure has been extended to the assay of  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Ni}^{2+}$ . The apoenzyme from alkaline phosphatase (zinc-metalloenzyme) recovers its activity by adding zinc ions, and thus  $\text{Zn}^{2+}$  can be determined. Ascorbate oxidase from cucumber contains  $\text{Cu}^{2+}$  ions and the apoenzyme of the enzyme recovers its activity by addition of  $\text{Cu}^{2+}$ .

### Assay of Inhibitors

**Determination of organic compounds** Organophosphorus, carbamates, and chlorinated pesticides inhibit cholinesterase (acetylcholinesterase or butylcholinesterase). This inhibition of cholinesterase accounts to a large extent for the effectiveness of organophosphorus insecticides in the control of harmful insects, and for their toxicity to warm-blooded animals. The activity of cholinesterase decreases in proportion to the amount of pesticides present. The activity of cholinesterase can be assayed by measuring acetic acid produced by use of a pH stat approach or by measuring the choline produced by choline oxidase enzyme reaction (measurement of  $\text{O}_2$  decrease). For fluorimetric detection, *N*-methylindoxyl acetate is suitable for the assay of pesticides as a substrate. The substrate is hydrolyzed by cholinesterase from

**Table 1** A list of enzymes that are inhibited by various inorganic ions

Peroxidase	$\text{Cd}^{2+}$ , $\text{Co}^{2+}$ , $\text{Cu}^{2+}$ , $\text{Fe}^{2+}$ , $\text{Fe}^{3+}$ , $\text{Mn}^{2+}$ , $\text{Pb}^{2+}$ , $\text{Cr}_2\text{O}_7^{2-}$ , $\text{S}^{2-}$
Urease	$\text{Ag}^+$ , $\text{Cd}^{2+}$ , $\text{Co}^{2+}$ , $\text{Cu}^{2+}$ , $\text{Hg}^{2+}$ , $\text{Mn}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Pb}^{2+}$
Xanthine oxidase	$\text{Ag}^+$ , $\text{Hg}^{2+}$
Liver esterase	$\text{F}^-$

various sources to the highly fluorescent *N*-methyl-indoxyl ( $\lambda_{\text{ex}} = 430 \text{ nm}$ ;  $\lambda_{\text{em}} = 510 \text{ nm}$ ).

Dichlorodiphenyltrichloroethane (DDT) inhibits carbonic anhydrase at the amount of micrograms at which other inhibitors are inactive. Carbonic anhydrase catalyzes the hydration of carbon dioxide to carbonic acid. The activity of the enzyme is assayed by measuring the  $\text{CO}_2$  liberated by dehydration in a Warburg manometer or a  $\text{CO}_2$  gas-selective electrode. DDT inhibits the enzyme, causing a decrease in the rate of  $\text{CO}_2$  liberation.

Ascorbic acid inhibits catalase in concentrations as low as  $2 \times 10^{-6} \text{ mol l}^{-1}$ . Very low concentration of  $\text{Cu}^{2+}$  ions accelerates the rate of inhibition. The inhibition of ascorbic acid to catalase occurs in the presence of  $\text{Cu}^{2+}$  ions. The activity of catalase can be monitored by the decrease of  $\text{H}_2\text{O}_2$  substrate or increase of  $\text{O}_2$ . For fluorimetric detection of  $\text{H}_2\text{O}_2$ , the decrease in fluorescence of scopoletin or the increase in fluorescence of diacyldichlorofluorescein upon reaction with  $\text{H}_2\text{O}_2$  are preferably monitored.

**Assay of inorganic compounds** There have been many methods that are based on the inhibitions of inorganic compounds for enzyme-catalyzed reactions. A list of enzymes that are inhibited by various inorganic ions is shown in **Table 1**. Generally, the specific determination of one inorganic compound inhibitor in the presence of others is impossible. Usually, a prior separation or masking procedures are performed. Thiosulfate and cyanide are generally

used as masking agents for  $\text{Ag}^+$  or  $\text{Hg}^{2+}$ , and  $\text{Ni}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Fe}^{2+}$ , respectively. The choice of masking agent, however, will depend on interfering inorganic compounds, pH, the substrate and enzyme, and so on. The use of appropriate masking agents will allow the researcher to develop specific procedures for very low concentration of the inorganic compounds of interest.

## Enzyme Immunoassay (EIA)

Enzymes have become one of the most popular labels for immunoassay. Nowadays, enzyme-labeled antigen and antibodies were employed as alternative to radioisotope-labeled materials in immunoassay. The class of immunoassays that employ an enzyme as a label is known as enzyme immunoassays. This is described in a separate article.

## Introduction

The first recorded use of essential oils was probably by the Egyptians who employed them for a range of purposes including medicinal, cosmetic, in religious

ceremonies, and for embalming the dead. About the same time, the Chinese were using herbs and aromatic plant extracts for medicinal purposes and their procedures were, eventually, assimilated into Indian Ayurvedic medicine. After the fall of the Egyptian empire, the ancient Greeks assumed much of the Egyptian knowledge and essential oils were employed by Hippocrates in aromatherapy. In due course, Greek medicine was taken up by the Romans who were impressed by the power of fragrances and also used them enthusiastically in aromatherapy. Subsequent to the dissolution of the Roman Empire and the resurgence of the Arabian empire, the use of essential oils was continued in the manner of the Romans and during this period an efficient distillation process was developed for their extraction.

During the dark ages, the monks in their monasteries persisted with the use of herbs for medicinal purposes and, although they did not recognize the nature of their activity as such, they used the antibacterial and antipesticide properties of many essential oils to cleanse wounds and control infestation. During the renaissance, the holistic approach to medicine, pioneered by Hippocrates, came back into vogue and Paracelsus used herbs (the knowledge of which largely came from folk remedies) to effect a cure for leprosy. The term aromatherapy was introduced by the French perfumer Gattefosse and appeared to have arisen from a personal experience after burning his hand in the laboratory. He treated his hand with pure lavender oil, which, apparently, immediately eased the pain and the burn subsequently healed with no infection and little or no scarring. This technique was subsequently used with great success in treating soldiers wounded in the First World War. Today, essential oils are widely used as perfumes, food flavors, and for medicinal purposes, but many of their bactericidal and antipesticide uses have been replaced by antibiotics and synthetic antipesticide and antifungal agents.

## The Chemical Nature of Essential Oils

Essential oils are composed of a very complex mixture of hundreds (sometimes thousands) of different substances, many often chemically related to one another. An indication of the complexity of an essential oil is afforded by the chromatogram of lime oil shown in **Figure 1**.

Only the major components are labeled in **Figure 1**, but the physiological activity of an oil (be it odor, bactericidal, fungicidal, etc.) is the net synergistic effect of all components including those present at the trace level. A synthetic lavender oil can be made up

**Figure 1** A chromatogram of lime oil (Superco, Inc.).

**Figure 2** The structure of isoprene.

from the major components, lavandol, borneol, terpineol, geraneol, and linalool mixed in the correct proportion to that of the natural oil. However, it will be found that the resulting mixture will not have nearly the same desirable effect on burns as the natural oil.

Many of the components of an essential oil are multiple derivatives of the hydrocarbon isoprene, the structure of which is shown in **Figure 2**.

Isoprene is a hydrocarbon and is the basic building block of many essential oils, either in the form of a terpene or in an oxygenated form (e.g., alcohol, aldehyde, etc.). The components of an essential oil can be roughly classed into the following types: terpenes (monoterpenes and sesquiterpenes), oxygenated compounds, alcohols, phenols, aldehydes, ketones, esters, lactones, coumarins, ethers, and oxides.

### Terpene Hydrocarbons

**Monoterpenes** A terpene molecule contains 10 carbon atoms (derived from two isoprene units) and at least one double bond. Terpene hydrocarbons are thermally labile and easily oxidized and, thus, citrus oils, which contain a high level of terpenes, do not keep well. Some terpenes are thought to have

anti-inflammatory, antiseptic, antiviral, and antibacterial properties, but, overall, the effect of the essential oil is a combination of the physiological activity of all the components. Some terpenes are considered to have analgesic properties or can act as stimulants. Some are said to stimulate mucous secretion and are consequently effective decongestants. It is clear that over the ages essential oils have been used extensively in medicine.

**Sesquiterpenes** Sesquiterpenes normally contain 15 carbon atoms and can have very complex pharmacological activity. An example of a sesquiterpene, farnesene, is shown in **Figure 3**. Farnesene is often found in chamomile and rose and many other floral essential oils. Farnesene has significant anti-inflammatory and antiallergy properties and, thus, in the past essential oils containing farnesene were used for the same purposes that aspirin and ibuprofen are used today.

Chamazulene, the structure of which is also shown in **Figure 3**, has similar pharmacological properties and is found in German chamomile.

### Terpene Alcohols

**Monoterpene alcohols** Examples of these types of essential oil component are linalool, citronellol, and terpinol; the structure of the latter is shown in **Figure 4**.

These substances are commonly found in lavender, rose, geranium, and juniper oil. The monoterpene alcohols have antiseptic, antiviral, and antifungal

properties and are claimed to give an uplifting or energizing impact on the user.

**Sesquiterpene alcohols** Sesquiterpene alcohols are not commonly found in essential oils but, like *bisabolol* (found in the German chamomile) are anti-allergen, anti-inflammatory, and can also act as liver and glandular stimulants. Other essential oils that contain sesquiterpene alcohols are sandalwood oil (the active alcohol being  $\alpha$ -sanatol, the structure of which is included in **Figure 4**), oil of ginger, patchouli oil, vetiver oil, and carrot seed oil.

**Aldehydes** It is the aldehydes present in melisa, lemon grass, and citronella oils that give them their citrus-like fragrance. They have antifungal, anti-inflammatory, and disinfectant properties together with some sedative effects. They are usually employed in aromatherapy at less than 1% levels contained in a neutral solvent; as at higher concentrations they can cause skin irritation. Aldehydes are generally unstable as they are easily oxidized and tend to be thermally labile; as a consequence, the oils must be stored with care.

**Ketones** In general, the ketones found in essential oils can be very toxic (e.g., thujone, the structure of which is shown in **Figure 5**, and pinopamphone). However, at appropriate concentrations they have useful therapeutic properties, promoting the secretion of mucous and inducing cell and tissue regeneration as well.

Hyssop, eucalyptus, and rosemary contain moderate amounts of ketones and are employed extensively in aromatherapy. The ketone italdione is used to aid skin regeneration, wound healing, and to help reduce wound scars, stretch marks, etc., as well act as a mutolytic (promoting mucous secretion).

**Esters** The esters that naturally occur in essential oils usually provide the fruity and fragrant character to the oil. Some esters are reported to have antifungal

**Figure 3** The structures of farnesene and chamazulene.

**Figure 4** The structures of terpineol and  $\alpha$ -santalol.

**Figure 5** The structures of thujone and linalyl acetate.

and antimicrobial activity as shown by geranium oil. Others have been shown to act as sedatives and antispasmodics. An example of an ester commonly present in many essential oils is linalyl acetate, the structure of which is also included in **Figure 5**. Most of the therapeutic effects are relatively mild and such esters can be used in moderation with some confidence.

**Ethers** There are very few ethers commonly found in essential oils and those that do are phenolic in nature. The two most important are anethol, which is found in aniseed, and methyl chavicol, which is found in basil and tarragon. The structures of anethol and methyl chavicol are shown in **Figure 6**.

**Oxides** The oxides in essential oils, e.g., 1,8-cineol (eucalyptol) in eucalyptus oil, are largely responsible for the expectorant characteristics of such oils. The structure of eucalyptol is given in **Figure 7**.

**Lactones and coumarins** Lactones are the result of molecular ring formation involving an ester group by the elimination of water, an example of which is the formation of  $\gamma$ -butyl lactone given below:

The amount of lactones and coumarins contained in essential oils is relatively small. Many can act as

**Figure 6** The structures of anethol and methyl chavicol.

**Figure 7** The structures of cineol and helenalin.

sedatives and antispasmodics and some lactones, coumarins, and ketones exhibit neurotoxic effects and can cause skin sensitizing and irritation. Helenaline (the structure of which is included in **Figure 7**), is a component of arnica oil and is probably the agent present in the oil that is responsible for its anti-inflammatory properties. Some coumarins (e.g., furocoumarin and bergaptene that are found in bergamot oil) can be phototoxic and, thus, if used topically, great care should be taken to avoid the treated area from being exposed to bright sunlight.

**Phenols** Phenols that occur in essential oils usually contain an aliphatic side chain; for example, thymol, eugenol, and carvacrol, whose structures are shown in **Figure 8**.

Phenols are inherently antiseptic, antibacterial, and, thus, act as disinfectants. Consequently, those essential oils that have high phenol content must be used at low concentrations and over relatively short periods of time. As they have good antiseptic properties, phenols are also skin and mucous membrane irritants, examples of which are cinnamon and clove oil.

## Raw Materials

Essential oils can be stored in many different parts of a plant. The different botanical sources of essential oils together with examples are summarized in **Table 1**.

**Figure 8** The structures of thymol, eugenol, and carvacrol.

**Table 1** Storage sources of essential oils

<i>Morphological site</i>	<i>Essential oil</i>
Buds	Black current, clove
Flowers	Hyacinth, jasmine, lavender, rose, ylang-ylang
Fruits	Citrus, juniper berry, vanilla
Seeds	Anis, cardamom, coriander, nutmeg
Leaves	Buchu, geranium, lavender, patchoili, peppermint
Bark	Cinnamon
Wood	Cederwood, sandalwood
Roots, rhizomes	Angelica, orris, vetiver
Resins	Galbanum, laudanum, myrrh, olibaum

The actual oils are stored in specific plant organs from which they need to be released and then extracted. There are three plant organs in which oils are stored and these are glands, oil cells, and cavities.

### Glands

Glands are the name given to cellular excrescences on some surface area of the plant that holds the essential oil. Examples of plants that have these are thyme, marjoram, rosemary, sage, and savory. It is interesting to note that all these plants are members of the Lamiaceae family.

### Oil Cells

Oil cells are individual plant cells that are filled with components of the oil and which must be broke open to release the oil.

Examples of plants that have oil cells are laurel and cinnamon of the family Lanraceae and lemon, orange, and other citrus plants of the family Rutaceae.

### Cavities

Cavities are tubular spaces developed in plants due to cell deterioration. Cavities occur in anis, caraway, coriander, and fennel (members of the Umbelliferae family) and the needle oils of the Abies and Pinus.

## Extraction Techniques for Essential Oils

There are three general methods of extraction: distillation, expression (largely employed for the extraction of essential oils from citrus fruits), and solvent extraction. The selected process depends on the nature of the raw material more than on the nature of the essential oil. An exception would be supercritical extraction with liquid carbon dioxide, which is an ideal method of extraction but, unfortunately, extremely expensive and thus can only be used in very special circumstances. The process chosen for extraction can have a profound effect on the quality of the oil produced.

### Distillation

There are a number of different types of distillation, which, although basically the same process, vary in detail to suit specific types of raw material and specific types of oil.

**Water distillation** The raw material is completely immersed in water and the temperature raised to boiling point. The oil and the water then distill from the matrix (largely by steam distillation) but steam

*per se* is not introduced into the still. On cooling the distillate, the oil and water separate and the oil is selectively removed. One advantage of this method is that the oil is never raised above a temperature of 100°C and, thus, thermal decomposition is minimized. For thermally labile oils, the temperature can further be reduced by distilling under reduced pressure. The separated water is also a product and sold as 'floral waters', e.g., rose water, lavender water, etc. If the basic oil contains a large number of esters, they will probably break down under extended exposure to hot water by hydrolysis and, consequently, an alternative extraction method would be appropriate.

**Steam distillation** In steam distillation, hot steam is forced through the matrix of raw material, opening the cavities in which the oil is held, and volatilizing the oils. This process is, in fact, pure steam distillation. The oil separates from the water in the distillate and is collected. As the steam is under pressure, the temperature can be carefully adjusted to provide the maximum rate of extraction with minimum thermal decomposition. Lavender oil, which is thermally, labile can be extracted by steam distillation without thermal damage.

The two processes can be combined by filling the still with the raw material and water and distillation carried out, not by heating the still, but by passing steam through it. This combined process has the combined advantages and disadvantages of both techniques.

**Hydrodiffusion** Hydrodiffusion is basically a modification of steam distillation that provides a shorter processing time, a higher yield, and greater steam economy. It differs from the conventional steam distillation in that the steam is passed into the top of the container, passes through a bed of botanical material supported on a grill, and is condensed below the extraction bed. Other than the improvements mentioned above, the process has the same properties as the conventional form of steam distillation.

**Cohobation** Some oils are partially soluble in water and so when the oil separates from the water distillate a portion of the oil still remains in the aqueous fraction. This typically happens with rose oil as one of the important components is phenyl ethyl alcohol, which remains in the water after separation. Thus, phenyl ethyl alcohol and any other water-soluble components must be either distilled from the distillate or extracted by some other means and added back to the separated oil. This process has been given the name of cohobation.

## Expression

Expression techniques largely involve crushing or macerating the botanical material to release the essential oils so that they can be washed free from the plant matrix. There are a number of methods used but, basically, they all involve maceration followed by washing.

**Cold pressing** In this process, the oils are expressed under high pressure and not heated at all. This process is simple, inexpensive, and particularly suitable for oils that are thermally labile. Some of the oil is inevitably retained by the plant matrix but the amount may not be significant.

**Écuelle à Piquer extraction process** The Écuelle à Piquer process (the prick/stick/prod process) is mainly used for the extraction of citrus fruits. The fruit is placed in a spinning container that has spikes on the sides which puncture the oil cells in the fruit. The oil from the punctured cells, together with the juice and pigments, pass down the center of the device into a collection area. The liquid is removed and the oil that floats on the surface of the aqueous layer is separated by decantation.

**Machine abrasion** This method is similar to that of the Écuelle à Piquer process and is used largely for citrus fruits. The machine strips off the outer peel, which is taken away by a stream of water and then passed into a centrifugal separator. Although the separation is relatively fast the oils obtained are in contact with the broken cell contents (which contain different enzymes) for a significant time and, thus, the oil can easily be degraded enzymatically.

**The maceration process** The maceration method also includes a type of solvent extraction process. The flowers are immersed in hot oil that causes the membranes to become ruptured, releasing the essential oil. The essential oil dissolves in the hot oil and the botanical residues separated from the mixture by filtration or centrifugation and the essential oil recovered by distillation.

## Solvent Extraction

Solvent extraction is a very gentle way of isolating the essential oils from a botanical matrix. Consequently, they are employed with thermally labile materials that cannot accommodate elevated temperatures such as jasmine, hyacinth, narcissus, and tuberose. An added advantage is that in many cases solvent extraction also reduces enzymatic

degradation. The solvents commonly employed are hexane, petroleum ether, methanol, and ethanol, all of which are readily available and relatively inexpensive. A solvent-extracted oil is highly concentrated and is close to a true representation of the natural fragrance of the parent flower.

There is some criticism of the solvent-extracted oil in that it may contain high boiling contaminants present in the original solvent that may amount to between 2% and 20% (this was particularly so when benzene was used as the extracting solvent). Consequently, for aromatherapy, solvent-extracted oils may not be acceptable. However, if hexane is used as the extracting solvent, solvent residues in the essential oil can be reduced to less than  $10 \text{ mg l}^{-1}$ , which is generally acceptable.

**Supercritical carbon dioxide extraction** Supercritical carbon dioxide extraction is a relatively recent process and yields products of extremely high quality. The process is, however, relatively expensive due to high cost of liquid carbon dioxide. The critical temperature of carbon dioxide is  $31^\circ\text{C}$  and the critical pressure just over 1000 psi. Critical carbon dioxide is an excellent solvent for essential oils. Due to the relatively low temperature of the extraction, it can easily handle thermally labile oils without degradation and in addition it is chemically very inert and so does not react with any of the essential oil components. The essential oil is easily recovered from the extract by reducing the pressure in a controlled manner and allowing the carbon dioxide to evaporate. The extraction is carried out in a pressurized container constructed from heavy duty stainless steel at  $\sim 35^\circ\text{C}$  and  $\sim 1000$  psi. The equipment can also be very expensive.

**Enfleurage extraction** Enfleurage extraction involves the use of a high boiling semisolid solvent in the form of highly purified, odorless animal fat. The apparatus consists of an enclosure frame carrying glass shelves that are covered with purified lard. The freshly picked flowers or other plant material are laid on the shelves and pressed into the fat. The flowers are allowed to remain in the enclosure for a few days to allow the essential oil components to diffuse into the fat. The extracted flowers are then removed and replaced with a fresh supply.

When the concentration of essential oil in the fat has reached a maximum, the fat and essential oil are extracted with alcohol removing the oil from the fat, which is then used to make soap. The alcoholic solution is then carefully evaporated leaving the essential oil as the residue. This process is labor-intensive and obviously very costly, but is still used

for specifically extracting the essential oils of tuberose and jasmine.

## The Analysis of Essential Oils

Today, essential oils are almost exclusively analyzed by chromatographic techniques; mostly by gas chromatography, but if very high boiling components are present, by liquid chromatography. Chromatographic techniques provide very high resolution (necessary for highly complex mixtures) and very high sensitivity so that traces of materials can be separated and quantitatively measured with a fair degree of accuracy. If the chromatograph is associated with a mass spectrometer, then the trace component can also be identified. Chromatographs are expensive, but are a necessary analytical tool for the essential oil chemist.

### The Basic Gas Chromatograph

A block diagram representing the basic gas chromatograph is shown in Figure 9. The instrument consists of a number of units: the gas supplier, the flow controllers, the sample injector, the column situated in an oven, the detector (also situated in an oven), the detector electronics, and finally an appropriate display unit.

**Gas supplier** The mobile phase or carrier gas supply may consist of a single gas such as helium, or may include other gases (depending on the detector chosen), such as hydrogen and air for the flame ionization detector.

**Flow controllers** Many detectors are flow sensitive and, thus, a flow controller may be essential. The controllers are simple pneumatic devices that will maintain a constant mass flow rate independent of the column temperature or column impedance.

**The sample injector** The sample injector can be a simple septum injector and a hypodermic syringe that can place the sample directly on to the column or a high-pressure sample valve (that can be manually or mechanically operated) fitted with an appropriate sample loop.

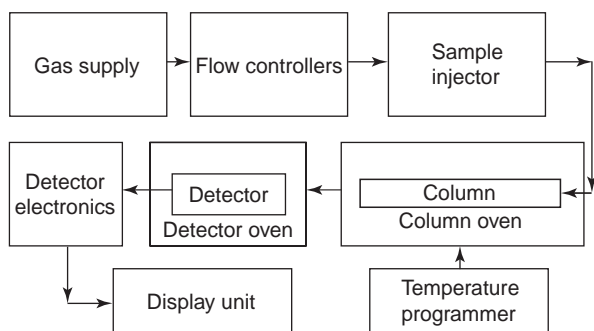

**The column and column oven** The column oven controls the column temperature and, thus, the rate at which the solutes migrate through the column.

**The temperature programmer** Increasing the column temperature increases the speed of solute migration through the column and shortens the analysis time for mixtures that contain solutes that extend over a wide range of molecular weight or polarity. The temperature of the column must be continuously increased during chromatographic development in a carefully controlled manner. This device can increase the temperature of the oven at a chosen rate and holds the oven at a specified temperature for a defined time before returning to a preset starting temperature.

**The detector and detector electronics** The detector and its electronic processor provide an electrical response that is linearly related to solute concentration as it leaves the column. Thus, the elution time can be measured and the concentration profile of an eluted solute can be monitored. The most common detectors are the flame ionization detector, the katharometer, and the electron capture detector.

**The display unit** The display units can be a potentiometric recorder, a computer printer, or, for very fast separations, a cathode ray tube. Modern instruments digitize the detector signal and pass it to a computer where the data are stored and processed and the results printed out directly on the printer. There are, however, many laboratories that still use potentiometric recorders and manually process their data.

**The analytical procedure** In a gas chromatographic analysis, the column temperature and temperature program is set appropriately for the sample to be analyzed. A solution of the sample is made up in a volatile solvent that will elute very early in the chromatogram and well away from the solutes of interest, the concentration usually being between 1% and 5% v/v. The sample (normally between 0.5 and 5  $\mu$ l in volume) is placed on the column, either with a hypodermic syringe directly through the septum of the injector onto the column, or into a sample loop of a sample valve, which by rotation allows the carrier gas to carry the sample onto the column. The

**Figure 9** The basic gas chromatograph.

**Figure 10** The basic liquid chromatograph.

temperature program is initiated, the separation developed, and the chromatogram monitored by a recorder or stored on the computer disk. The data can be processed by the computer or the analysis calculated from the recorder chart.

### The Basic Liquid Chromatograph

A diagram of the basic liquid chromatograph is shown in **Figure 10**.

The chromatograph consists of six units: the gradient system, the pump, the sample valve, the column, the detector, and the recorder.

**The solvent supply and gradient system** Solvents are stored in glass or stainless steel vessels (usually two or three in number) and are best sparged with helium to eliminate dissolved air. Some systems employ a vacuum-assisted permeable membrane device for degassing. This method, however, is inferior in performance to helium sparging, which, in particular, must be used with microbore and capillary columns. If the mixture contains substances that cover a wide range of polarity, then gradient elution must be employed. There are two types of gradient programmers: programmers that have a pump for each solvent and are programmed to mix the solutes at high pressure and programmers that have a mixing valve prior to a single pump and, thus, the different solvents are mixed at low pressure.

**Sample valve** There are two types of sample valves: the internal loop valve and the external loop valve. The former are for use with small bore columns (columns having internal diameters of less than 1.5 mm) and the latter are used for larger diameter columns up to semipreparative columns. Sample volumes generally range from 0.5 to 5  $\mu$ l.

**Column ovens** The thermal capacity of a liquid chromatographic column is much higher than that of the gas chromatograph as the specific heats of liquids are much greater than those of a gas. As a result it is often necessary to preheat the mobile phase before it

enters the column to maintain good temperature control. Air is usually employed as the thermostating medium although a liquid thermostating medium would be more thermally effective but renders column changing more difficult.

**Detectors** The most common liquid chromatography detectors are the ultraviolet detector, the fluorescence detector, and the refractometer. Liquid chromatography detectors have less sensitivity (defined as the minimum detectable concentration) than gas chromatography detectors (in fact several orders of magnitude less). The fluorescence detector is probably one of the most sensitive detectors and the refractive index detector the least sensitive. In special applications (e.g., carbohydrate analysis), the light scattering detector is growing in popularity but, unfortunately, although universal in response, has a sensitivity (as defined previously) that is only slightly better than that of the refractive index detector.

**Analytical procedure** The analytical procedure is very similar to that used in gas chromatography, except that sample valves are exclusively used to inject samples onto the column.

## Introduction

Alcohol ( $\text{CH}_3\text{CH}_2\text{OH}$ ), more correctly known as ethanol or ethyl alcohol to distinguish it from the generic group of alcohols, is one of the most important individual organic compounds readily available in virtually unlimited quantities. It has been described as one of the most versatile of compounds, being widely used as a solvent, a germicide, a beverage, an antifreeze, a fuel, and perhaps most importantly, as an intermediate for the synthesis and production of other organic compounds.

Fermentation has been used to produce ethanol since ancient times, alcoholic beverages certainly having been known to the Pharaohs of ancient Egypt. It has been suggested that the name 'alcohol' derives from the Arabic words 'al' and 'kohl' used to describe an ancient preparation used to darken hair that may have contained ethanol. There is also some suggestion that Noah had a vineyard where a form of alcoholic beverage was produced.

## Ethanol Manufacture

Ethanol is manufactured by three main processes: indirect hydration, direct hydration, and fermentation.

### Indirect Hydration

In this process, ethene (ethylene) is passed into sulfuric acid to form mono- and diethyl sulfates, which

may then be hydrolyzed to give ethanol. Reactions [I]–[IV] show how this occurs:

### Direct Hydration

Ethene and water are mixed and passed over a catalyst (phosphoric acid on silica) at a temperature of  $300^\circ\text{C}$  and a pressure of  $\sim 70$  atm:

### Fermentation

The process known as fermentation involves the breakdown of sugar-based substances using yeasts of various types and is the oldest method known:

Although the total volume of ethanol produced worldwide by this process is less than that produced by the methods described above, it is probably the most important from an analytical viewpoint as most analytical work is associated with fermentation ethanol in the form of alcoholic beverages.

## Physiological Properties

The physiological properties of ethanol are well known. It has an odor and taste that are generally considered pleasant. Ethanol has marked hypnotic properties and depresses activity in the upper brain

**Table 1** Some physical properties of ethanol

Property	Data
Boiling point (at 1 atm, °C)	78.32
Freezing point (°C)	−114.1
Density ( $d_4^{20}$ ) (g ml <sup>−1</sup> )	0.7893
Viscosity (20°C, cP)	1.17
Refractive index ( $n_D^{20}$ )	1.36143
Solubility (water)	Miscible, all proportions
Flash point (°C)	12

even though it gives the initial impression of being a stimulant. Ethanol can be toxic if consumed to excess (the lethal dose in rats is 13.7 g per kg of body weight) but it is markedly less toxic than the other members of the homologous series.

## Physical Properties

Ethanol is a clear, colorless liquid. Its physical properties derive mainly from the presence of the hydroxyl group, infrared (IR) studies indicating that ethanol exists in the liquid state mainly in a dimeric form. The most important physical properties of ethanol are given in Table 1, some of which are important in the analytical chemistry of ethanol.

## Chemical Properties

The chemical properties are also of importance in certain of the procedures for ethanol determination. The hydroxyl group is the important component in the structure of ethanol, since all of the chemical properties of ethanol derive essentially from that group. From an analytical viewpoint, the most important property is the relative ease with which the molecule can be oxidized to give acetaldehyde (ethanal) and, in some cases, acetic acid (ethanoic acid). The pathway is shown in reaction [VII]:

## Environmental Considerations

Ethanol is a flammable liquid, its vapor concentrations being explosive in the range 3.3–19.0% (v/v) in air. However, flammability is not a serious problem in the industrial environment providing there is reasonable ventilation, which also prevents ethanol from causing severe problems as an industrial poison. The compound is reported to be detectable by nose at ~350 ppm, while higher levels of ~5000–10 000 ppm can cause irritation to the eyes and mucous membranes of the upper respiratory tract.

Concentrations in excess of these values soon become intolerable, causing severe coughing and laceration. However, as ethanol is readily oxidized in the body to water and carbon dioxide, it is not an accumulative poison. Ethanol poisoning normally results from the consumption of liquid ethanol in alcoholic beverages rather than from inhalation. It is this distinction that governs the main areas of application required for ethanol determination, namely measuring concentration levels in alcoholic beverages of all types and measuring blood ethanol levels in humans after the consumption of alcoholic beverages. These two principal areas will be considered in detail.

## Types of Alcoholic Beverage

### Beer

There are four areas in the brewing of beer where ethanol measurement is of vital importance. These are: (1) duty payment, (2) trade returns, (3) quality control, and (4) high-gravity beer cracking. Note that the level of ethanol in beer (including high-gravity beer) is 2.5–12.0% (v/v), while ethanol levels in some other beverages, i.e., ‘shandy’ and ‘alcohol-free’ types of beer and all soft drinks, fall in the range 0–1.5% (v/v).

**Duty payment** In most countries, excise duty is payable on the basis of the original gravity (OG) of beer.

**Trade returns** In the UK, the ethanol content of spoiled beer must be assessed by the customs and excise authorities prior to return of excise duty.

**Quality control** The modern brewing process requires that beer be passed through extensive lengths of piping, which can lead to dilution of beer with washing solutions.

**High-gravity beer cracking** It is now the case that most beer is initially brewed to an alcoholic strength up to three times the required level. The high-gravity beer is diluted with water to give the required strength and this dilution is controlled by the ethanol content, which must be monitored regularly during the dilution process.

### Wines and Spirits

European Community (EC) regulations require that the ethanol concentration in beverages falling in this group should be displayed on bottle labels. The excise duty payable on wine and fortified wine depends

on the ethanol concentration range, the ranges being: (1) <15% (v/v), (2) 15–18% (v/v), (3) 18–22% (v/v), and (4) >22% (v/v). Similar rules apply to distilled spirits where the range system applies up to 96% (v/v), although most spirits contain between 35% and 50% (v/v).

## Analytical Methodology

The analytical chemistry of alcoholic beverages, of which the determination of ethanol is only one facet, continues to develop. However, several methods of analysis for ethanol are available and tradition, government legal requirements, and convenience, taken together or separately, usually govern the choice of method. These methods include: (1) distillation and specific gravity measurement, (2) gas–liquid chromatography, (3) IR spectrometry, (4) headspace techniques, (5) enzyme methods, (6) chemical (colorimetric) methods, and (7) refractometry. These methods are now considered in turn.

### Distillation

The distillation method is the benchmark for all other procedures and is officially approved by excise authorities in most countries, particularly when any form of litigation is involved. The procedure described below is that approved in the UK for the determination of OG values of beer. Essentially the same procedure is used for other beverages. Details are as follows:

A sample of beer at 60°C is shaken and then filtered to remove dissolved gases (primarily carbon dioxide). The beer (100 ml) is distilled using standard distillation equipment to give a distillate volume of ~85 ml. The distillate is made up to 100 ml with water, the temperatures being maintained at 60°C. The specific gravity of the distillate is measured using traditional methods, i.e., the density bottle, pycnometer or hydrometer, or, as is increasingly the case, using electromagnetically induced oscillation techniques (see below). In addition, the residue in the distillation vessel is made up to 100 ml and its specific gravity also measured giving the 'Residue Gravity' value. The 'Spirit Indication' is calculated from the reduction in specific gravity from 1.000 00 resulting from the ethanol present in the distillate being multiplied by 1000. This value is then converted from statutory tables to the 'Gravity Lost' value. The OG value is calculated by adding the 'Residue Gravity' to the 'Gravity Lost' value.

For samples other than beer, i.e., wines and spirits, the experimental procedure, while essentially the same as for beer, is modified in two important

aspects, namely the temperature for density measurement is 20°C and the ethanol value is obtained from UK Customs and Excise Laboratory Alcohol Tables.

The determination of the specific gravity of the various distillates and residues is clearly a key element in the determination of ethanol by distillation. Such determinations by specific gravity bottle or pycnometer are well established and will not be described here. However, the use of hydrometers for this purpose now requires that only hydrometers complying with BS 5471:1977 can be used for official analyses in the UK.

More important at the present time is the increasing use of electronic devices for density measurement. Such instruments allow the liquid density to be determined with high precision and accuracy using the principle that when a column of liquid is electromagnetically excited, its period of oscillation is related to its density by the relationship:

$$D = A(T^2 - B) \quad [1]$$

where  $D$  is the density,  $T$  is the period of oscillation, and  $A$  and  $B$  are calibration constants. The procedure requires that a small U-tube is filled with 0.7 ml of the distillate and the sample temperature controlled to  $\pm 0.01^\circ\text{C}$ . The sample is electromagnetically excited and the period of oscillation determined by comparison with a highly accurate reference frequency produced by a crystal oscillator. It is claimed that the results of this procedure are unaffected by viscosity, volatility, or turbidity. This sometimes allows the direct determination of ethanol, although such results must be treated with caution depending on the degree of dissolved solids, e.g., sugars, in the sample, which could affect the density of the sample and thus affect the ethanol value. In the context of ethanol determination, the instrument microprocessor allows the direct display of ethanol content.

An assessment has been reported of the distillation procedure that suggests that the overall accuracy of the method is  $\pm 2\%$ . However, the procedure is laborious (~30–40 min per determination) and requires a high degree of skill on the part of the analyst. However, it is the method preferred by many analysts and is the official method by which disputes regarding ethanol content are judged.

### Gas–Liquid Chromatography

The use of gas–liquid chromatography (GLC) as a general analytical technique is now well established and it is rare to find a modern analytical laboratory without such a facility, although many smaller breweries and wineries still do not have such equipment. As an important analytical technique in its own right,

it is discussed elsewhere in this encyclopedia and as such will not be considered here in detail. However, ethanol can be determined by standard GLC techniques in most situations appertaining to alcoholic beverages. Ethanol is a volatile substance that lends itself to analysis by GLC, flame ionization detection normally being chosen because of its insensitivity to water. Polar columns are the norm, poly(ethylene glycol) types usually being chosen. Internal standard techniques are normally adopted, usually using one of the propanols as an internal standard. Advantages of GLC are the high degree of selectivity achievable, especially using modern capillary and megabore columns, and the high speed of analysis compared with distillation. Accuracy and precision are about the same or marginally better than distillation. GLC is now accepted as a standard procedure for beer analysis in the US but the rather high cost of the equipment and the necessity for relatively high technical skills on the part of the analyst still preclude its use by small beer and wine makers.

### Infrared Spectroscopy

Infrared spectrometry is now extensively used both to characterize and determine organic compounds. As a technique it is considered elsewhere in this Encyclopedia. Its specific use to determine ethanol in alcoholic beverages is not widespread although near-IR instruments dedicated to this purpose are available. However, such instruments are extremely costly and can normally only be justified by a large throughput of samples. However, IR spectroscopy is widely used for breath alcohol determination, particularly in the UK, where the method is approved as the definitive procedure for evidential use. In this context, the absorption bands normally utilized are the asymmetric C–H stretching band at  $2950\text{ cm}^{-1}$  and the complex C–O stretching band at  $1050\text{ cm}^{-1}$ .

### Headspace Techniques

The volatile nature of ethanol makes it eminently suitable for headspace analysis. The principle on which the method is based is that of partition theory, i.e., that the concentration of a volatile species in the headspace above a solution is proportional to the concentration of that species in solution. Procedures based on this principle must therefore be classed as 'indirect', but nevertheless they have some advantages over direct methods, the most important being that the procedure separates volatile species from the numerous nonvolatile compounds commonly found in alcoholic beverages. As most sensors used in instrumentation for the determination of ethanol are at best semispecific and are usually oxidative in

principle, this feature is most advantageous, as many of the nonvolatiles, e.g., sugars, are readily oxidized.

Several instruments are available that operate on this principle. All involve the passing of a flow-controlled gas (usually air or nitrogen) stream through the beverage (which may require dilution). The gas stream is fed to a suitable sensor, comparisons usually being made with similar streams generated from standard ethanol solutions. In one type of instrument, the sensor is a ceramic material coated with a catalytic agent that is sensitive to oxidizable substances. The sensor forms part of a Wheatstone bridge circuit. When an oxidizable species is present the ceramic surface of the sensor is heated, causing a change of resistance in the sensor, which in turn generates an out-of-balance current in the Wheatstone bridge circuit. In another instrument based on the headspace principle, the sensor is a fuel cell that generates a potential when exposed to readily oxidizable compounds. This sensor is somewhat more selective than the ceramic types, as, of the numerous chemical species found in alcoholic beverages, it is sensitive only to aldehydes and alcohols.

Instruments of the above type are nowadays usually microprocessor controlled and give a direct reading of the ethanol content of the sample. They are relatively costly instruments, much of the cost resulting from the necessity for precise control of sample temperatures, as the headspace concentration of ethanol is very susceptible to temperature change, the variation being  $\sim 6\%$  per  $^{\circ}\text{C}$ . However, such instruments allow a high throughput of samples, and have the added advantage of being portable, allowing on-site ethanol determinations as and when required.

### Enzyme Methods

In recent years, numerous methods of ethanol determination have been developed, several of which are a variation on the following theme. Ethanol is oxidized to ethanal using nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ) and alcohol dehydrogenase according to reaction [VIII]:

Normally this equilibrium lies well toward ethanol but is easily displaced quantitatively to ethanal formation by increasing the pH or removing the ethanal from the system. The NADH produced is usually determined spectrophotometrically by its absorbance at 334, 340, or 365 nm.

More recently, the use of electrodes incorporating alcohol oxidase has been used for ethanol assay. In this situation, the ethanol is oxidized in the presence of oxygen to give hydrogen peroxide according to

reaction [IX]:

The hydrogen peroxide formed can be measured amperometrically with an appropriate electrode.

Many publications have appeared on the themes outlined above, but the approach has been dogged by the instability of the enzymes, leading to the need for frequent electrode calibration. Work is continuing and it is possible that in due course this approach might gain acceptance for ethanol assay. To date, however, the enzymatic approach has had little impact on the more well-established procedures of gas chromatography and distillation.

### Chemical Methods

Ethanol can be assayed in solution using oxidizing reagents, potassium dichromate being the most commonly used reagent. The color change from yellow (chromium(VI)) to green (chromium(III)) is used, usually with a spectrophotometric endpoint. The ethanolic solution is refluxed with excess acidified ( $\text{H}_2\text{SO}_4$ ) potassium dichromate until no further reaction occurs and the chromium(III) assayed as indicated.

Although this method is little used in the alcoholic beverage industries, mainly because of its lack of specificity, it has found extensive application in breath and blood ethanol analyses associated with drink-driving cases. This method will be considered in more detail below.

### Refractometry

Refractometers have long been used to determine the alcoholic strength of beer in particular, usually in conjunction with specific gravity determinations. It has been reported that it is possible to determine OG, ethanol content, and Residue Gravity of beers by simultaneously measuring the density of the beer and its refractive index and applying a set of empirical equations to the data. Fully automated instruments are available utilizing this approach.

## Breath and Blood Ethanol Determination

Since 1960, the need for reliable methods of ethanol determination for blood samples taken from vehicle drivers has been driven by the introduction of legislation in many of the developed countries and an increasing number of Third World countries. This legislation introduced legal limits for the level of blood ethanol for car, lorry, and public vehicle drivers. In the UK, this value is currently 80 mg of

ethanol per 100 ml of blood, but the value varies considerably around the world.

The legislation brought with it the need for two ethanol determinations to be made, the first a screening test that established a *prima facie* case that the suspect had a blood ethanol value at or in excess of the legal limit and would allow the law enforcement agencies to apply a second, more stringent, assay that could be used evidentially, i.e., a value that would be acceptable as evidence in a Court of Law.

### The Breath and Blood Ethanol Relationship

It has been shown that, under controlled conditions, there is a direct relationship between the level of ethanol in the breath and that in the blood. Ethanol, after ingestion, is absorbed into the bloodstream largely through the small intestine. Blood circulation carries the ethanol to the lungs where the ethanol equilibrates rapidly with lung air. The relationship established is such that at body temperature (which essentially thermostats the sample), the UK legal limit of 80 mg of ethanol per 100 ml of blood gives rise to a breath sample containing 35  $\mu\text{g}$  of ethanol per 100 ml of breath. It is, therefore, essential that the sample taken be such that it represents a deep lung sample and it is necessary to ensure that sufficient time has elapsed between the subject's last drink and sampling, as mouth samples taken immediately after a drink would be artificially high. This elapsed time varies worldwide, but is usually  $\sim 20$  min.

### Screening Procedures

Screening of suspects in drink-driving cases is normally carried out by police officers with little or no knowledge of analytical chemistry. It is, therefore, of paramount importance that the procedure adopted demands the minimum of experimental skill, is easily applied under difficult circumstances, and gives a result with a relative accuracy of  $\sim \pm 10\%$  (w/v). Two methods are currently adopted, both involving the sampling of breath, one involving a version of the chemical test (potassium dichromate) referred to above, and the other, more recent procedure, utilizing a sensor and microelectronics to both sample and assay the breath sample.

**'Blow-in-the-bag' screeners** Early breath screeners consisted of a glass tube containing a precise amount of silica gel impregnated with acidified ( $\text{H}_2\text{SO}_4$ ) potassium dichromate. The packing (which is yellow) was contained between graduation marks, with a further graduation within the outer marks indicating a 'fail' situation. When a sample of breath containing ethanol was blown through the tube, the dichromate color changed from yellow to green (chromium(III)). If the

green color extended beyond the graduation mark, the subject was considered to have failed the test, and could be further examined by more sophisticated procedures. The volume of breath used was clearly critical, and this was measured by the subject blowing through the tube, ideally with one deep breath, until a standard volume plastic bag attached to the tube was completely filled.

**Electronic screeners** Difficulties with the above methods, arising mainly from the problems deriving from the rather poor color change of the dichromate tubes, and uncertainty about an individual's ability to fill the plastic bag reproducibly, provided the impetus for the development of a more sophisticated approach to breath screening.

Most developed countries now use an electronically controlled breath sampling and monitoring system that incorporates a sampling tube into which the suspect blows (Figures 1 and 2). Incorporated into the tube are a pressure transducer and indicator light

to ensure that a deep lung sample has been taken. When the indicator light shows that a sufficient exhalation of breath has occurred, a sampling valve is activated which takes a fixed volume of the breath sample and feeds it to the sensing device, which in most cases is a platinum catalyst fuel cell.

This type of fuel cell sensor provided a major breakthrough in breath screening analysis for several reasons. These include relatively low cost, robustness, sensitivity, and perhaps, above all, the fact that the cell generates its own electrical output, only requiring power for signal amplification purposes. A fuel cell thus consists of two catalytic (usually platinum) surfaces supported on a suitable porous material (commonly sintered poly(vinyl chloride)) impregnated with an electrolyte such as aqueous sulfuric acid. Oxidation occurs at the working surface, and an equivalent reduction (usually of atmospheric oxygen) occurs at the counter-electrode.

The ethanol in the breath sample is oxidized in the fuel cell as follows according to reaction [X]:

This gives an electrical output that is linearly proportional to the ethanol content up to four to five times the legal limits. The results are usually displayed digitally as blood ethanol values in whatever units are appropriate for the particular country, although in the UK a system of colored lights is used to represent different levels of ethanol.

### Evidential Methods

**Gas chromatography** Ethanol may be assayed directly in blood samples using gas chromatography, the procedure being similar to that used for alcoholic beverages. An internal standard procedure is usually adopted, propan-2-ol normally being used as internal standard. However, the method has fallen out of favor due to the invasive nature of the sampling procedure (blood sample) and it is now used only sparingly. However, in cases where the data from other methods are disputed, it is still used as the final arbitration procedure and can usually be demanded by a suspect who wishes to challenge analytical data obtained by other methods.

**Infrared spectroscopy** Infrared spectroscopy has become the most widely used, although not the only, method of evidential breath and blood analysis. It has the considerable advantage of being extremely rapid and lends itself well to vapor (breath) analysis. These features are of particular importance as most governments specify that the time taken for the total analytical process, which includes the required calibration procedure, should not exceed ~5 min. In

**Figure 1** A roadside breath screening test being administered. (Photograph from The Scotsman Publications Ltd.)

**Figure 2** A fuel cell-based evidential breath analyzer.

essence, the suspect will be required to provide a deep-lung breath sample in much the same way as described for screening, although the sample delivery tube is heated to prevent condensation of water in the breath. The breath sample is fed to an IR cell where absorbance measurements are made, frequencies being selected using optical filters. The instrument most widely used in the UK utilizes such a system, the asymmetric stretching frequency at  $2950\text{ cm}^{-1}$  being used. The possibility of interfering substances (only acetone (propanone) is likely to be present naturally in sufficiently high levels to cause interference) is obviated by the incorporation of an additional sensor, usually of the Taguchi (tin oxide) type. This latter sensor produces an offset signal and the test procedure is aborted. Direct blood ethanol determination by gas chromatography is usually resorted to in such circumstances.

Organisation Internationale de Metrologie Legale (OIML) regulations have in recent times demanded a considerably higher degree of selectivity and this has resulted in the development of more sophisticated optical systems allowing measurement at lower frequencies, particularly at  $1050\text{ cm}^{-1}$ , where selectivity for ethanol is high. Detector sensitivity at this frequency is low but modern electronics appear to have coped with this situation, several instruments with measurements made at this lower frequency now being available.

**Fuel cell-based evidential monitors** Although the IR spectroscopic approach to evidential breath analysis appears to have gained general acceptance in most developed countries, the need for a more robust instrumental option has been apparent in the needs of some developing countries. To this end, some instrumentation is currently available using a fuel cell sensor of the type used in screening devices. These units are essentially the same as screeners, but with more sophisticated electronics for signal analysis, automatic (usually motorized) sampling systems, and a means of printing data in a form acceptable for evidential use. Their main advantage is that, compared to the relatively fragile optical system of an IR unit, the fuel cell sensor is extremely robust and instrumentation of this type can withstand a considerable degree of maltreatment.

## Other Areas Requiring Alcohol Analysis

### Yeast Production

Bakers yeasts used in the making of bread are produced by propagation in closed vessels. The yeast is

held as a suspension by continuous stirring and aeration, molasses and suitable nutrients (nitrogen source) being used as the growth medium. Under these conditions (pH  $\sim 4.4$ ,  $32^\circ\text{C}$ ), the food source is metabolized to carbon dioxide. However, should the rate of aeration become insufficient to sustain this process, the fermentation will become anaerobic and ethanol will be produced with a diminution in the efficiency of yeast growth. Headspace techniques are usually applied to monitor ethanol formation, i.e., GLC and fuel cell-based methods, although solution analysis can also be used.

### Vinegar Manufacture

The production of vinegar involves an initial anaerobic alcoholic fermentation followed by an aerobic fermentation using acetic acid bacteria to convert the ethanol to acetic acid. The ethanol concentration is vital to the overall efficiency of the process and must be monitored regularly using procedures similar to those indicated for yeast production.

### Controlled Atmosphere Fruit Storage

The large-scale storage of fruit, particularly apples and pears, is now carried out under refrigeration ( $\sim 4^\circ\text{C}$ ) and in a chemically controlled atmosphere where the oxygen concentration is reduced to below 4% (v/v). The onset of fruit deterioration is heralded by the production of ethanol, which may be detected by online analyzers of the headspace type.

### Introduction

Solvent extraction is a classical analytical technique used to determine the contents of various inorganic and organic species. Inorganic compounds are usually extracted after complexation with organic ligands. The technique also enables preconcentration of solutes and their separation and finds practical applications in various industries, including nuclear, metal processing, petrochemistry, pharmaceutical,

and others. Depending upon the extraction system considered, different ligands may be used, normally dissolved in organic diluents. Due to environmental problems connected with the use of organic solvents, novel systems with more environment-friendly solvents have been proposed for various new preconcentration methods.

Various phenomena should be considered in solvent extraction. The analytical purposes and determination of complex stoichiometry are the classical problems. The amphiphilic character of many extraction reagents must also be taken into consideration when studying kinetics and extraction mechanism.

### Types of Reagents and Extraction Reactions

Physical extraction is seldom used in practice; extraction reagents are normally used. These can be

divided into acidic, basic, and solvating (neutral) extractants.

Acidic extractants can be further subdivided into simple organic acids, e.g., carboxylic acids, phosphoric acids, phosphonic acids, phosphinic acids, thiophosphorus acids, and sulfonic acids, and chelating reagents, e.g., hydroxyoximes, 8-hydroxy-(thio)quinolines,  $\beta$ -diketones, nitrosophenols, and pyridylazonaphthols. These reagents transfer metal cations into the organic phase in the form of uncharged complexes, e.g., copper(II) with hydroxyoximes (HL):

where subscripts 'w' and 'o' denote the aqueous and organic phases, respectively.

The distribution ratio ( $D = C_o/C_w$ ) is the function of reagent concentration and equilibrium pH:

$$\log D = \log K_{\text{ex}} + 2 \log [\text{HL}]_o + 2\text{pH} \quad [2]$$

An increased acidity of the aqueous phase shifts the equilibrium of eqn [1] to the left. Due to this, acidic extractants cannot transfer large amounts of metal cations, and the back-extraction is accomplished with mineral acids of appropriate concentration.

Extraction can be used to separate and pre-concentrate the analyte component(s), to recover valuable components from aqueous solutions (hydro-metallurgy, biotechnology), and also to determine the stoichiometry of extracted complexes. In the latter case, the relations  $\log D$  versus pH and  $\log D$  versus  $\log \text{HL}$  are considered, and the composition of the complex can be determined from the slopes of the linear parts of these relationships.

The extractant can form associated forms, usually dimers, and the extracted complex can be solvated by undissociated extractant molecules and can undergo polymerization. Thus, the more complex eqn [3] can be presented:

Values of  $n$ ,  $m$ , and  $p$  can be determined from extraction data by slope analysis or by using computer programs.

The extraction constant  $K_{\text{ex}}$  present in eqn [2] is the function of several individual constants characteristic of steps such as the partitioning of the ligand ( $P_{\text{HL}}$ ), the dissociation of the ligand ( $K_a$ ), the overall complex stability constant ( $\beta_{\text{CuL}_2}$ ), and the partitioning of complex ( $P_{\text{CuL}_2}$ ):

$$K_{\text{ex}} = \beta_{\text{CuL}_2} K_a^2 P_{\text{CuL}_2} P_{\text{HL}}^{-2} \quad [4]$$

Thus, solvent extraction can also be used as a research method to determine certain physical-chemical data.

Basic reagents are usually primary, secondary, and tertiary amines or their ammonium salts with a different length and the structure of the alkyl group(s). Amines require protonation before they can act as extractants. For example,

They can only extract anions from acidic solutions, by transferring bulky anions to the organic phase in the form of ion-pairs. For example,

An alternative mode of extraction involves an addition reaction. For example,

The interpretation of extraction data must take into account the formation of various chlorocomplexes  $\text{ZnCl}_i^{2-i}$ , where  $i = 1, 2, 3, 4$ , and a more complex equation for  $\log D$  is obtained. For example, for eqn [7]:

$$\log D = \log(K_{\text{ex}} \cdot \beta_2) + 2 \log [\text{R}_3\text{NHCl}]_o + 2 \log [\text{Cl}^-]_w - \log \left( 1 + \sum_{i=1}^4 \beta_i \cdot [\text{Cl}^-]_w^i \right) \quad [8]$$

The stability constants of various metal anion complexes  $\beta_i$  are given in the literature. Usually, reliable data can be obtained for typical analytical diluted solutions, but such estimations are not reliable for concentrated solutions that contain various ions.

Quaternary ammonium salts react without protonation and the extraction is not sensitive to the acidity of the aqueous phase.

Solvating reagents such as neutral compounds (e.g., ethers, ketones, alcohols, and esters of carboxylic acids, alkyl phosphates, phosphonates, phosphinates, phosphine oxides, and phosphine sulfides) and also esters of pyridinecarboxylic acids and certain benzimidazole derivatives that have electron-withdrawing substituents form solvates with extracted neutral species. For example, dialkylpyridine-3,5-carboxylates extract Cu(II) at pH 3 from concentrated chloride solutions:

Solvating reagents can also extract charged species together with counterion(s). For example, tributyl

phosphate or trialkylphosphine oxides extract zinc(II) from hydrochloric acid solutions:

Instead of protons, metal cations can also be transferred to the organic phase.

As in the case of ion-pair extraction with basic reagents, the formation of various chlorocomplexes must be taken into consideration.

Solvating reagents can also extract bulky anions, e.g.,  $\text{CrO}_4^{2-}$ ,  $\text{MoO}_4^{2-}$ , and anionic chlorocomplexes, by means of the hydration mechanism. For example,

The preprotonation of solvating reagents, such as alcohols, and the extraction of anionic species are also possible:

The parallel transfer of extracted species by means of various mechanisms also occurs.

The solvating reagents are usually less selective than acidic extractants and the transferred complexes are not as well defined. A high concentration of salts and/or the presence of complexing anions are needed to obtain the efficient extraction of metal species. The drawbacks are coextraction of acids and water. The back-extraction is usually carried out with water.

Certain reagents can be considered bifunctional, i.e., 8-hydroxyquinoline and its derivatives and alkylpyridine carboxylates. The former, depending on the pH of the aqueous phase and the type of metal cation, can act as a chelating acidic extractant, forming chelates with copper(II) and zinc(II), or after protonation as a basic reagent, forming ion-pairs with anionic zinc(II) chlorocomplexes. Alkylpyridine carboxylates act as solvating reagents that extract copper(II) from chloride solutions at pH 3, but after protonation they extract palladium(II) efficiently from HCl solutions. The use of bifunctional extractants or the mixtures of basic and chelating extractants or solvating (S) and chelating (HL) extractants enables the extraction of metal species from chloride solutions as ion-pairs or solvates. Scrubbing with water causes a transfer of metal cation into chelate from which the cation can be stripped with sulfuric acid. Thus, mixed extractants enable a transfer of metals from chloride to sulfate

solutions. For example, for copper(II) extraction: extraction step:

scrubbing of chlorides with water:

back-extraction:

Extractants are often used with modifiers (e.g., hydrophobic alcohols, alkylphenols, sterically hindered esters of carboxylic acids, and tributyl phosphate). Modifiers are used for two different reasons: first, to increase the solubility of extractants and their complexes and to avoid the formation of the third phase, and second, to modify the extraction properties, i.e., the extraction and stripping abilities. The first option is usually exploited in systems that contain various amines. The second option is associated with hydroxyoximes and the formation of tailored blends, which optimize the extraction-stripping properties and adjust them to the aqueous feed, i.e., to the acidity and concentration of copper(II). Modifiers that form hydrogen bonds with hydroxyoxime molecules decrease their extraction ability but facilitate back-extraction with acids. Weak hydroxyoxime or  $\beta$ -diketone extractants (e.g., 2-hydroxy-5-alkylbenzophenone oxime) can also act as modifiers of strong hydroxyoxime extractants (e.g., salicylaldoxime and its alkyl derivatives).

## Extractants as Amphiphilic Compounds

Extractants that have a hydrophobic substituent(s) and a hydrophilic fragment(s) (Figure 1) show an amphiphilic character, adsorb at water/organic solvent interfaces, and decrease the interfacial tension. Their interfacial activity depends on the type of hydrophilic and hydrophobic groups, the number and structure of the alkyl group, and the type of solvent. Thus, they behave in a similar way to hydrophobic surfactants in surface tension reduction and aggregation. However, in typical extraction systems, chelating extractants show moderate interfacial activity and decrease the interfacial tension to only  $15\text{--}25\text{ mN m}^{-1}$ . Strong acidic extractants and protonated alkylamines exhibit the highest interfacial activity, while solvating reagents and neutral amines are on the opposite side of the scale.

**Figure 1** Extractants as amphiphilic substances.

All factors that lead to hydration, protonation, and dissociation of the polar group decrease the hydrophobicity of extractant molecules and polarize them. The decrease in hydrophobicity makes the extractant molecules less compatible with the nonpolar organic phase, and enhances the attractive interaction between extractant head group(s) and water. Thus, the forces that draw the extractant molecules from the bulk organic phase to the interfacial region increase adsorption. On the other hand, phenomena such as solvation or aggregation of the extractant molecules result in the formation of species that are less surface-active than monomeric extractants. The adsorption, however, needs an appropriate balance of forces acting on both sides of the interface, and excessively strong interactions of the extractant head groups with water molecules favor the dissolution of extractant in the aqueous phase and inhibit the adsorption at the hydrocarbon/water interface.

The density of population and orientation of surfactants at the interface depends upon their structure and concentration and the type of diluent. The effect of the latter is decisive. Molecules of aromatic hydrocarbons that have  $\pi$  electrons compete with extractant molecules for access to the hypothetical interface, and solvating diluents disturb the adsorption of extractant molecules and the penetration of

**Figure 2** Interfacial zone with adsorbed extractant molecules (A and B denote systems with aliphatic and aromatic hydrocarbons).

**Figure 3** Isotherms of interfacial tension and surface excess for acidic chelating extractant at octane/water (O/W) and toluene/water (T/W) interface.

extractant hydrophilic groups in the aqueous layers (Figure 2). The density of extractant population, or the surface excess  $\Gamma$ , can be calculated from the Gibbs isotherm alone or by the coupling of this isotherm with various equations that correlate the surface tension with extractant concentration in the organic phase, e.g., the Szyszkowski equation. The density of population increases with the extractant concentration only for a limited range of low concentrations, assuming a constant value at the saturated interface (Figure 3). The interface already becomes saturated at bulk extractant concentrations of  $10^{-3}$ – $10^{-2}$  mol l $^{-1}$ , and even earlier in the presence of solvating diluents.

Modifiers also have some hydrophilic groups and adsorb at liquid–liquid interfaces. Thus, they compete with extractant molecules for access to the interface and presence in the adsorption layer, thus decreasing the interfacial concentration of extractant molecules. The same phenomenon occurs when different extractants are present in the extraction system.

Some extractants that have acidic groups, e.g., sulfonic, phosphonic, phosphinic, and also some basic and solvating extractants in the systems containing acidic aqueous phase, form reverse micelles (Figure 4). The formation of reverse micelles appears

**Figure 4** Reverse micelles in organic phase. (Adapted from Nitsch W and Plucinski P (1990) Two-phase kinetics of the solubilization in reverse micelles. *Journal of Colloid and Interface Science* 136: 338–351.)

to be a general phenomenon for acidic extractants and occurs even at very low concentrations, e.g.,  $10^{-5}$  and  $10^{-3} \text{ mol l}^{-1}$  for dinonylnaphthalene sulfonic acid and di(2-ethylhexyl)phosphoric acid, respectively. Even tributyl phosphate forms reverse micelles in contact with solutions of HCl and  $\text{HNO}_3$ . The presence of the water pool in the core of reverse micelles causes nonspecific transfer of water-soluble components, thus decreasing the selectivity of extraction and disturbing the interpretation of the equilibrium extraction data. However, the presence of reverse micelles may increase the rate of extraction. This phenomenon is exploited in the so-called micellar extraction, especially for the extraction of biochemicals that need an aqueous environment to keep them stable.

Under certain conditions, in the presence of a cosurfactant, e.g., butanol, and/or alkaline aqueous phase, reverse micelles swell, accepting a large amount of water, and transparent and stable microemulsions are formed. Microemulsion can also be obtained when typical surfactants with cosurfactant are present in the organic phase. Such systems enable the rapid extraction of germanium(IV) and gallium(III) with alkyl derivatives of 8-hydroxyquinoline, while classical extraction needs days of phase contact.

## Kinetics and Mechanism of Extraction

Extraction is performed by the diffusional flow of a metal across the interface between two liquid phases, accompanied by the chemical reaction of metal complex formation. The diffusion of the species that participate in the chemical reaction is of great significance, as are the locations in which the chemical reaction proceeds, and the rate of complexation.

**Figure 5** Extraction pathways for acidic extractant with different location of complexing step.

Depending on the relative rates of the chemical and diffusion steps, the reaction can proceed in the kinetic, diffusion, or mixed regime, the entire process being controlled by the rate of the chemical step, a diffusion process, or by both kinetics and diffusion. Thus, under very good hydrodynamic conditions, e.g., upon vigorous agitation, the influence of the diffusion can be substantially eliminated and the kinetic results can be used to discuss the reaction mechanism. This conclusion is not always true, and the use of typical surfactant micellar aqueous solutions with extractants dissolved (solubilized) in micellar pseudophase (micelles) and inorganic species dissolved in aqueous pseudophase mimic the extraction systems effectively and the diffusion processes are totally eliminated.

The chemical step can occur in the bulk of the aqueous phase or aqueous pseudophase, in the bulk of the organic phase or in the micelle and/or at the actual interface, or at the hypothetical interface of the micelles. **Figure 5** shows the possible extraction pathways in typical extraction for metal recovery with an acidic extractant. Metal ions, such as hydrophilic and charged species, are insoluble in typical organic phases. Thus, the version of complex formation in the organic phase can be disregarded as long as the formation of reverse micelles and W/O microemulsions is avoided. However, such an option is possible in the extraction of organic compounds. The interfacial reaction can be understood as the reaction in the real interfacial zone of  $\sim 2 \text{ nm}$  thickness or as the reaction in a thin boundary layer in the aqueous phase.

The location of the reaction step depends on extractant surface activity and hydrophobicity, metal concentration, and hydrodynamics (agitation intensity). Low metal concentration and high hydrodynamics, together with high surface activity and the low solubility of the extractant in the aqueous phase (i.e., high hydrophobicity), favor the interfacial reaction. However, the reaction place may also depend on experimental conditions, i.e., the method used for the studies. In general, case reaction

**Figure 6** Reaction scheme of metal complexing from acidic sulfate solutions with hydroxyoxime extractants. (Adapted from Szymanowski J (1993) *Hydroxyoximes and Copper Hydrometallurgy*. Boca Raton: CRC Press.)

proceeds simultaneously both in the bulk of the aqueous phase and at the interface (Figure 6). The contribution of the interfacial reaction increases in a homologous series of extractants, e.g., with an increase in the alkyl group length.

In systems with reverse micelles/microemulsion, the transfer of extracted species occurs both through the macroscopic interface between dispersed and continuous phases and through the large microscopic interface between water pools and extractant hydrophilic groups in the cores of the micelles. The transfer of water with hydrophilic species is possible due to reverse micelles forming at the interface and sucking the aqueous phase.

Although adsorbed molecules of extractants are well oriented at the interface, the interfacial reactions occur more slowly, as recalculated for the same volume, than reactions in the aqueous phase. The extraction of palladium(II) from HCl solutions with dialkyl sulfides is a classic example of a very slow process. Modifying the extractant structure by adding a hydrophilic hydroxyl group and/or a phase transfer catalyst, e.g., trialkylamine or quaternary ammonium salt, increases the rate of extraction. The addition of sulfonic and phosphoric acids to hydroxyoximes may enhance the rate of copper extraction due to the formation of reverse micelles and the development of the microscopic interface. The  $\alpha$ -acyloin oximes that form an intermediate complex 'that has a five-member ring' with copper(II) increase the rate of extraction of aromatic hydroxyoximes. The addition of surfactants may cause both retardation and acceleration of extraction. If the interfacial tension is decreased, surfactants cause an increase in the interfacial surface area in dispersed systems. When they adsorb at the interface, they cause an additional

interfacial resistance, but when the charge is opposite to that of the intermediate metal complex, they enhance the transfer due to electrostatic attraction.

## New Methods of Extraction and Solute Preconcentration

Sample pretreatment is still currently the weakest link, the time-determining step in the whole analytical procedure and the primary source of errors. The increasing need for the determination of numerous analytes at lower and lower levels and in increasingly complex matrixes makes sample pretreatment, especially trace enrichment, an indispensable step in many analytical procedures.

Trace enrichment can be performed by liquid-liquid extraction (LLE) or solid-phase extraction (SPE). Although SPE is a relatively more recent and popular technique, LLE is still one of the most versatile techniques for enrichment because of its advantages: it is simple to perform, requires simple and inexpensive equipment, has a high capacity for interfering compounds, has a high potential for chemical tuning, and separates by incorporating different specific reagents. The main drawbacks of LLE are the high consumption of solvents, the difficulty of automation, and the formation of emulsion.

Many efforts have been made to overcome these inherent drawbacks. There is also a tendency to develop analytical procedures for sample preparation that reduce or completely eliminate the use of organic solvents and decrease the number of operations. New processes are now being developed that employ aqueous-based systems. These use water effectively and with a marked reduction in the risk to

human health and the environment. The following new extraction processes can be considered:

- cloud point extraction (CPE),
- micellar enhanced ultrafiltration (MEUF),
- extraction in aqueous biphasic systems (ABS),
- homogenous liquid–liquid extraction (HLLE),
- extraction to ionic liquids (IL),
- supercritical fluid extraction (SFE),
- continuous flow liquid–liquid extraction (CPLLE),
- supported liquid membrane (SLM) extraction, and
- microporous membrane liquid–liquid extraction (MMLLE).

When surfactants aggregate in aqueous solutions, they form micelles even at relatively low concentrations, i.e., above the critical micelle concentration. An increase in temperature causes the dehydration of nonionic surfactants that have a hydrophilic polyoxyethylene chain, e.g., Triton X-114, dissolved in aqueous solutions, the aggregation of micelles, and therefore the clouding of the solution at the cloud point (CP) and the separation of the surfactant-rich phase (SRP), as in **Figure 7**. The process can be reversed by cooling. The volume of SRP is 1–2 orders lower than the remaining aqueous micellar phase and depends on the surfactant concentration and the temperature of separation. The SRP volume increases with an increase in the surfactant concentration but decreases with an increase in temperature above the CP. An increase in temperature also causes a decrease in water content in the SRP, which becomes more hydrophobic. The phase can be considered a water solution in the surfactant that is micelle-like in structure. The CP of nonionic surfactants can be modified by the surfactant structure and the addition of electrolytes. An increase in surfactant hydrophobicity and an addition of salting-out electrolyte, e.g., NaCl, decreases CP. Salting-in electrolytes, such as KSCN, have the opposite effect. The cooling of solutions that contain zwitterionic surfactants, e.g.,  $R(CH_3)_2N^+-(CH_2)_3SO_3^-$ , also causes the clouding and separation of the SRP. Species that have some hydrophobicity (e.g., organic compounds, biochemicals, and

proteins) can be first solubilized in micelles and then transferred to the SRP. Ions must first be neutralized with hydrophilic complexing reagents. The CPE technique is used for the extraction and preconcentration of metal ions after the formation of sparingly water-soluble complexes as an initial step for their determination by various instrumental methods as well as for the separation and purification of various biochemicals, especially proteins.

Coacervation, the clouding of solutions that contain typical anionic surfactants, can be induced by the addition of an electrolyte or by acidification and can also be used for preconcentration. However, the phenomenon cannot be reversed as easily as the CP.

Substances that are solubilized in surfactant micelles can be separated by ultrafiltration through membranes whose pores are smaller in diameter than the micelle size. For a membrane molecular weight cut-off from 1 to 50 kDa, the rejections are  $\sim 98\%$ . The stream of water-containing monomeric molecules of surfactant (permeate) flows through the membrane. The remaining solution (retentate) contains solutes solubilized in micelles. The MEUF process is used for the separation of organic substances and various ions, the latter after their previous complexation.

Aqueous biphasic systems that contain two or more hydrophilic polymers, especially polyoxyethylene glycol–dextran–water or polymer and salt, and mainly polyoxyethylene glycol–inorganic salt–water, are classical techniques for recovering and separating biochemicals such as proteins and nucleic acids. They also appear (especially the polyoxyethylene glycol–inorganic salt–water system) to have some utility for solvent replacement in the extraction of metal ions and small organic molecules. The benefits of ABS are connected with the aqueous environment of both separated phases, which are formed without the involvement of any organic solvent.

In HLLE, a small volume (microliter range) of water-immiscible liquid is separated from 10 to 100 ml of homogeneous aqueous solution containing perfluorooctanoate ion. This phenomenon is induced by a change in pH or by the addition of counter-cations, such as quaternary ammonium ions.

**Figure 7** Cloud point extraction.

The solute species in the sample solution is concentrated in the sedimented phase, and a 100–1000-fold increase in concentration is achieved. This method is used to concentrate vital compounds such as hemoglobin, vitamin B<sub>12</sub>, and various metal ions. HLLE seems to be a simple and powerful preconcentration method for several instrumentation techniques, including capillary gas chromatography and capillary electrophoresis.

ILs, mainly quaternary ammonium salts with hydrophobic anions, e.g., 1-n-octyl-3-methylimidazolium hexafluorophosphate and tetrafluoroborate, are nonvolatile solvents that can be also applied in extraction. The selection of anions decides the IL hydrophobicity, the formation of a two-phase system with water, the solubility of ILs in water and of water in ILs, and the IL's hygroscopic properties. Up to now, the hydrophobic ILs that form separated phases with water contain potentially dangerous anions, such as PF<sub>6</sub><sup>−</sup> and BF<sub>4</sub><sup>−</sup>, which may decompose and produce fluoride ions. ILs are more viscous than typical solvents and may interfere with the transfer of ionic species. New applications for small-scale separations may emerge in the future.

SFE is a well-established process for the recovery of different organics, mainly nonpolar substances from various solid matrices. It allows the selective extraction of different chemicals without an additional clean-up step and uses small sample amounts. Supercritical carbon dioxide (SC-CO<sub>2</sub>) is a convenient solvent, due to its moderate constants ( $T_c = 31^\circ\text{C}$ ,  $P_c = 7.3\text{ MPa}$ ), nontoxicity, nonflammability, sufficient solvation power, and availability in pure form. SC-CO<sub>2</sub> is also used to extract various organic compounds from environmental aqueous samples. Quantitative removal requires the addition of low molecular organic modifiers such as alcohols to enhance the polarity of SC-CO<sub>2</sub>.

Automation and online connection to analytical instruments requires extraction to be performed in a continuous way and simultaneous with the flows of phases. The most successful techniques are MPLLE and SLM extraction (Figure 8). SLM enables extraction and back-extraction to be carried out in one continuous process due to the separation of flowing aqueous phases (the acceptor phase is stagnant in analytical applications) by a hydrophobic membrane, which is usually of polytetrafluoroethylene, and the organic phase immobilized in the pores of the membrane. The organic phase, used in small amounts in comparison with LLE, may contain sophisticated extractants called carriers. Membranes are impregnated by soaking in the organic phase. The analyte present in the donor phase (aqueous sample) is dissolved in the membrane phase or complexed

#### SLM extraction

#### MMLLE

**Figure 9** Simple and facilitated transport with solvating carrier of an aromatic compound having a phenolic group.

with the carrier, then transported via diffusion through the pores on the other side of the membrane and transferred to the acceptor phase. The aqueous phases have different acidities to keep analytes in neutral and charged forms in the donor and acceptor phases, respectively, in simple transport, e.g., of amines, phenols, or organic acids, or to form and decompose the complex in facilitated transport with carriers (Figure 9). The latter must be used for extraction of ionic species that are not soluble in the membrane without prior complexation. The SLM extraction is a dynamic process that is usually controlled by diffusion in the pores and that gives separations that are different to those for LLE, which is an equilibrium process. By incorporating specially designed carriers, a very high selectivity can be obtained with an enrichment level of over 100 in environmental samples. Using hollow fibers, enrichments of up to a few thousands were reported.

SLM extraction is well suited to automated interfacing with liquid chromatography and capillary

**Figure 10** Enrichment and separation setup for SLM extraction. electrophoresis. A miniature SLM device (Figure 10) consists of polypropylene hollow fiber with pores filled with an organic solvent, inserted and fastened in a cylindrical channel of the module. The sample is pumped on the outside of the hollow fiber, and the analyte is selectively enriched and trapped in the fiber lumen. The volume of the stagnant acceptor solution can be as low as 1–2  $\mu\text{L}$ , and is transferred through capillaries to chromatographic systems. Using devices with a flat membrane, the volume of the enriched sample is 10–15  $\mu\text{L}$ .

A new version of CPLLE can be performed as cross- and countercurrent flows of aqueous and organic phases separated by the microporous membrane (MMLLE) in the same devices used for SLM extraction (Figure 8). The organic phase wets the membrane better than an aqueous solution and enters the membrane pores. A leakage of the organic phase can be prevented by applying a suitably higher pressure on the aqueous side.

## Solvent Extraction: Multistage Countercurrent Distribution

C F Poole, Wayne State University, Detroit, MI, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Separations by partitioning between two immiscible liquids can be made more effective by using a cascade process. Suitable processes can be viewed as

continuous or discontinuous depending on how the liquid phases are contacted. Discontinuous processes are characterized by a number of separate equilibration steps followed by transfer of either or both liquid phases for further contact with the fresh liquid phase. This multistage partitioning process is referred to as a countercurrent distribution. Manual countercurrent distribution separations require little equipment beyond suitable vessels, such as test tubes or separating funnels, and use either decantation or

**Figure 10** Enrichment and separation setup for SLM extraction. A – peristaltic pump, B – membrane device with hollow fiber installed into fused silica capillary, C – inlet on the donor side, D – washing line used after enrichment, E – microinjection pump to transport the acceptor into loop F, G –  $C_{18}$  packed capillary column, H – detector window, I – splitter unit, J – high pressure pump. ## Solvent Extraction: Multistage Countercurrent Distribution

## Introduction

Separations by partitioning between two immiscible liquids can be made more effective by using a cascade process. Suitable processes can be viewed as

continuous or discontinuous depending on how the liquid phases are contacted. Discontinuous processes are characterized by a number of separate equilibration steps followed by transfer of either or both liquid phases for further contact with the fresh liquid phase. This multistage partitioning process is referred to as a countercurrent distribution. Manual countercurrent distribution separations require little equipment beyond suitable vessels, such as test tubes or separating funnels, and use either decantation or

pipettes for liquid transfer between vessels. This is a rather slow and tedious process whenever a significant number of equilibration stages are required for the separation. Martin and Synge introduced automated machines for countercurrent distribution in the 1940s. Craig and others improved upon these machines in the 1950s, resulting in widely used apparatuses with up to 1000 cells, although machines in the range of 50–250 cells were more common. At a later date, Albertsson introduced the thin-layer countercurrent distribution apparatus to reduce the settling time for liquid phases of similar density, such as those used in two-phase aqueous systems for the separation of biopolymers and particles. Akerlund improved upon this design by using centrifugal force for the separation of the two liquid phases. The technical development of automated countercurrent distribution machines had stopped by the 1990s, however, and these machines find little use today.

There are several reasons for the demise of countercurrent distribution as a separation technique. Shortly after the development of automated countercurrent distribution machines, Martin and Synge demonstrated that liquid–liquid partition separations could be performed more efficiently and faster by partition chromatography. Initially, paper chromatography, and later thin-layer chromatography, was adopted for analytical applications and columns for preparative separations. Eventually, the emergence of high-pressure liquid chromatography as a major separation technique for both analytical and preparative separations ended interest in multistage countercurrent distribution separations. Almost in parallel, in the 1970s, Ito began the development of several smaller and more efficient devices for countercurrent chromatography. Countercurrent chromatography differs from countercurrent distribution in the use of mechanical forces created by planetary motion of a coiled tube to stabilize one liquid phase, a stationary phase, while the other, a mobile phase, is continuously pumped through it. Distinct separation stages are not employed and the separation system need not be at equilibrium. In addition, it was found that many of the applications traditionally performed by countercurrent distribution could be transferred to countercurrent chromatography without difficulty.

Countercurrent distribution and countercurrent chromatography are distinguished from column chromatography by the absence of a solid stationary phase or support. Sorptive surfaces present few problems for the separation of small molecules but for macromolecules, multiple surface interactions can result in a loss of selectivity and/or denaturation of biopolymers. Cost savings for preparative

applications may be significant for liquid–liquid compared with liquid–solid systems. In addition, the range of additives that can be used in liquid–liquid systems is generally less restrictive and mechanisms more easily understood than in the case of column chromatography.

The general theory of countercurrent distribution is still of general interest since manual liquid–liquid extraction remains a common laboratory technique. In addition, countercurrent distribution models often provide a starting point for the explanation of separations by chromatography and continuous liquid–liquid extraction processes. A favorable feature of countercurrent distribution systems is that separations are completely predictable, once the solute distribution ratios and the phase ratio are known.

## Theory

Liquid–liquid extraction is an equilibrium process between two immiscible phases, described by a equilibrium constant, usually called the distribution constant or partition coefficient. The distribution constant,  $K$ , is defined as the ratio of the concentration of the substance in the two phases at equilibrium ( $K = C_U/C_L$ , where  $C_U$  is the concentration of analyte in the less dense (upper) phase and  $C_L$  its concentration in the more dense (lower) phase). The distribution or partition ratio,  $G$ , defined as the ratio of the solute masses in the two phases ( $G = m_U/m_L$ , where  $m_U$  is the mass of analyte in the less dense phase and  $m_L$  its mass in the more dense phase), is often more useful. The distribution constant and distribution ratio are related through the phase ratio,  $V$ , by  $G = KV$ . The phase ratio is the volume ratio of the liquid phases ( $V = \text{volume of the less dense phase}/\text{volume of the more dense phase}$ ).

A convenient way of analyzing the countercurrent distribution process is to calculate the amounts (in fractions) of a single component in the two phases based on the distribution ratio. In the initial two-phase system (number 0), the substance is distributed with the fraction  $p$  in the upper phase and  $q$  in the lower phase. By definition  $p + q = 1$ . Transfer of the upper phase from cell 0 to the lower phase of the next cell (number 1) results, after equilibration, in the distribution of the transferred fraction according to  $G = p/q$ . The fraction in the upper phase of cell 1 will become  $p^2$  and in the lower phase  $pq$ . A fresh upper phase is added to cell 0. The fraction  $q$  remaining in the lower phase will distribute itself into the upper phase and at equilibrium the fraction in the upper phase will be  $pq$  and in the lower phase  $q^2$ . The resulting distribution after 10 transfers in the

$pq^{10}$	$10p^2q^9$	$45p^3q^8$	$120p^4q^7$	$210p^5q^6$	$252p^6q^5$	$210p^7q^4$	$120p^8q^3$	$45p^9q^2$	$10p^{10}q$	$p^{11}$	Amount in upper phase
$q^{11}$	$10pq^{10}$	$45p^2q^9$	$120p^3q^8$	$210p^4q^7$	$252p^5q^6$	$210p^6q^5$	$120p^7q^4$	$45p^8q^3$	$10p^9q^2$	$p^{10}q$	Amount in lower phase
0	1	2	3	4	5	6	7	8	9	10	$i$
$q^{10}$	$10pq^9$	$45p^2q^8$	$120p^3q^7$	$210p^4q^6$	$252p^5q^5$	$210p^6q^4$	$120p^7q^3$	$45p^8q^2$	$10p^9q$	$p^{10}$	Amount in each tube

**Figure 1** Distribution of a component that partitions in the ratio  $p/q$  between the upper and lower phases after a countercurrent distribution with 10 transfers. The amounts are given in fractions, i.e.,  $p + q = 1$ . The amount in each cell is the combined mass in the upper and lower phases for each cell.

11 cells 0–10 is shown in **Figure 1**. Generally, the amount of material,  $T_{n,i}$  (in fractions), in cell number  $i$  after a countercurrent distribution with  $n$  transfers is given by

$$T_{n,i} = [(n!)/i!(n-i)!][G^i/(1+G)^n] \quad [1]$$

This relation can be used to calculate the distribution profiles for 100 and 1000 transfers with  $G$  values varied in steps between 0.05 and 20 (**Figure 2**). The resolution of peaks with various  $G$  values increases with the increase in the number of transfers ( $n$ ). This is due to the fact that the difference in the position (cell number) of the peaks is proportional to the number of transfers while the peakwidth only increases with the square root of the number of transfers.

Since virtually all the pure substance is contained in a region extending for  $3\sigma$ -values either side of the peak maximum, the peakwidth,  $W$ , can be approximately calculated by

$$W = 6\sqrt{nG}/(1+G) \quad [2]$$

This is true for symmetrical peaks, which will be the case when either  $n$  is large or  $G \sim 1$ .

The relative peakwidth expressed both as a number of cells and as a percentage of the total number of cells for different values of  $G$  and  $n$ , is summarized in **Table 1**. The space occupied by a single peak as a fraction of the total space available rapidly decreases as the number of transfers increases. As  $G$  becomes either large or small compared to 1, the separation factor approached the limiting values of  $n$  or 0. Thus, substances with large or small values of  $G$  will crowd together at the ends of the countercurrent train.

The most effective separation of two substances with distribution constants  $K_1$  and  $K_2$  is achieved when their peak maxima are symmetrically arranged

**Figure 2** The resulting countercurrent distribution profiles after (A) 100 and (B) 1000 transfers for substances with the indicated  $G$  values. The x-axis indicates the number of transfers ( $n$ ) and the y-axis the value for  $T_{n,i}$  expressed in fractions (see eqn [1]). The x-axis also relates the relative position of a substance with a defined value of  $G$  to the cells which it will occupy after a given number of equilibration steps.

**Table 1** The absolute peak width as the number of cells occupied,  $W$ , and percent of the total number of cells occupied by a peak ( $100W/n$ ) calculated for several values of  $G$  and  $n$ 

$n$	$W$	$100W/n$
$G = 1$		
50	21	42
100	30	30
1000	95	9.5
$G = 5$		
50	16	32
100	23	23
1000	71	7
$G = 10$		
50	12	24
100	17	17
1000	54	5.4

**Table 2** The number of transfers,  $n$ , in a countercurrent distribution necessary to separate two substances, 1 and 2, with a given separation factor  $\alpha$ . The phase ratio is selected such that the equality  $G_1 \cdot G_2 = 1$  is satisfied

Separation factor ( $\alpha$ )	Distribution ratios		Number of transfers ( $n$ )
	$G_1$	$G_2$	
2	0.709	1.414	264
3	0.577	1.732	110
4	0.500	2.00	70
9	0.333	3.00	30
16	0.250	4.00	20
25	0.200	5.00	16
36	0.167	6.00	14
49	0.143	7.00	12
81	0.111	9.00	10
400	0.05	20.0	6

around the middle of the distribution train, i.e., cell  $i = n/2$ . This occurs when the relation  $G_1 \cdot G_2 = 1$  at an optimum phase ratio of  $V = 1/\sqrt{(K_1 K_2)}$ . The ratio of  $K_1/K_2$  is the separation factor,  $\alpha$ , and is a measure of the ease of separating the two substances. The number of transfers necessary for virtually complete (more than 95%) separation for various  $\alpha$  values is calculated in Table 2.

The  $G$  value of a substance that has its maximum peak value in cell number  $i$  after  $n$  transfers is given approximately by  $G = i/(n - i)$ . The  $G$  value can also be obtained by comparing the amount of a substance in two consecutive cells, numbers  $i$  and  $i + 1$  by combining the expressions for  $T_{n,i}$  and  $T_{n,i+1}$

$$G = [T_{n,i+1}/T_{n,i}][(i + 1)/(n - i)] \quad [3]$$

The determination of  $G$  values from experimental data is of considerable importance, as it is the first step in the calculation of theoretical distribution curves to fit the data. When the  $G$  value is known,

the entire distribution curve can be calculated for any chosen value of  $n$  from eqn [1] using successive values of  $i$  from 0 to  $n$ . Comparison of the apparent  $G$  values over a distribution peak allows detection of the presence of impurities with slightly different  $G$  values.

## Operational Aspects

The standard method of operation in countercurrent distributions is known as the fundamental procedure. This basic process can be modified or extended in several ways.

### Fundamental Procedure

Shaking or agitation is used to equilibrate the sample between the phases in the first cell of the machine so that one phase becomes finely dispersed in the other. The fine dispersion facilitates the attainment of equilibrium by greatly increasing the interfacial area between the liquid phases. When the equilibration process is complete, agitation is stopped and the liquid phases allowed to separate. One phase (usually the upper) is then transferred quantitatively to the next cell of the apparatus, where it is brought into contact with a fresh volume of the stationary phase. Simultaneously, a fresh portion of upper (or lower) phase is introduced into the first cell of the apparatus, and agitation recommenced to bring about a second equilibrium of the sample between the phases in both cells. The alternate equilibration and transfers with introduction of the fresh mobile phase at each transfer are repeated until the initial portion of mobile phase has reached the last cell in the apparatus. The distribution is then complete and the cells emptied individually or grouped according to their contents.

### Recycle

If an appreciable section of the apparatus contains no sample components after completion of the fundamental procedure, the resolving power of the apparatus is not being fully utilized. This sample-free section, however, may be used for separation after completion of the fundamental procedure by making one more transfer operation. The mobile phase from the last ( $n$ th) cell being reintroduced into the first (cell 0) of the apparatus. The process can be continued in principle until the leading boundary of the fastest-moving component is about to overtake the trailing boundary of the slowest component. At this stage, all the cells of the apparatus contain sample components, and its potential resolving power is fully utilized. The recycle mode can be combined with

any of the withdrawal procedures (see below). In this way, completely resolved components are removed continuously from the apparatus in the mobile phase with fresh mobile phase added to replace the withdrawn phase. The calculation of theoretical curves for the recycling method are identical with those for the fundamental procedure, except that the number of transfers applied is greater than the number of cells in the machine.

### Single and Double Withdrawals

In the single withdrawal procedure, also known as elution countercurrent distribution, the number of transfers is unlimited. The fundamental procedure is completed as usual followed by one more equilibration and settling of the phases, with transfer and withdrawal of a portion of upper (or lower) phase. Unlike the method of complete withdrawal, a new portion of upper (or lower) phase is introduced into cell 0. The processes of equilibration, settling, and transfer are carried out again and a second portion of the upper (or lower) phase is introduced into cell 0. The process is repeated for any required number of cycles, or until all the sample components have emerged in the withdrawn phase. Double and alternate withdrawals of upper and lower phases are also possible. The combination of recycle and single withdrawal procedures is the most important countercurrent distribution technique.

The different method of operation makes the single withdrawal procedure suitable for the separation of samples with a different range of distribution ratios to those commonly separated by the fundamental procedure. Substances with high  $G$  values are easily eluted in the upper phase by this method while those with low  $G$  values need a greater number of transfers to be carried through the countercurrent distribution train. The opposite is true when the lower phase is withdrawn. The greater the number of transfers, the more diluted the sample components are when eluted from the countercurrent distribution apparatus.

### Continuous Feed

To increase sample throughput for preparative applications requires a continuous feed of sample solution into the distribution apparatus. In O'Keefe's method, the sample is introduced at or near the center of the distribution apparatus. After equilibration and settling, all upper phases are moved to the next cell at the left and all lower phases to the next cell at the right. The upper and lower phases from the extreme cells on the left and right are collected. Fresh upper and lower phases are added to these cells to restore the original number of systems. After

addition of a new portion of sample to the center of the apparatus, the cycle is repeated. Substances with  $G > 1$  will be recovered in the upper phases collected to the right and substances with  $G < 1$  in the lower phases removed to the left. Typically, the number of cells employed is small (e.g., 11 or less). The method is used primarily to purify and concentrate a single component in a complex mixture or to separate two-component mixtures (pure components withdrawn in the upper and lower phases).

A similar process, called Watanabe–Morikawa partitioning, employs a sample feed at the end of the apparatus. This is useful when only components with high or low  $G$  values are to be isolated.

### Gradient

In gradients, for example, ionic strength, pH, complexing agent, affinity ligands, etc., can be introduced using the single withdrawal method by sequentially adjusting the composition of the new upper (or lower) phase added to cell 0. A gradient can be started with the first cycle or at any cycle number in the separation.

### Solvent Systems

Solvent systems suitable for countercurrent distribution must always form two discrete liquid phases, and a finally divided suspension in one phase in the other must separate quickly into two bulk-liquid layers. These properties must be retained in the presence of appreciable amounts of sample. The two phases should, therefore, differ in density, neither should have a high viscosity, while the interfacial tension should not promote the formation of stable emulsions. Formation of emulsions, which separate only with difficulty with real samples, is the most serious practical problem. Solvent systems should be selected based on their selectivity for the separation. In addition, distribution ratios can be optimized by changing the phase ratio or distribution properties of the phases by using additives (e.g., pH, complexing agents, salts, polymers, etc.).

### Two-Phase Aqueous Systems

Separation by partition between two immiscible aqueous phases has been successfully applied to a large number of proteins, nucleic acids, and cellular particles such as mitochondria, chloroplasts, membrane vesicles, and whole cells. The phase systems are made up of two different water-soluble polymers, dextran and poly(ethylene glycol), dissolved in water and complemented with suitable buffers, salts, and sucrose. Highly selective adjustment of the distribution process is possible by linking an affinity

ligand to one of the phase-forming polymers. This then serves to concentrate the selected substances in one of the phases. In two-phase aqueous systems, particles are separated according to their surface properties, for example, surface charge, hydrophobicity, and biospecific interactions. In this case, the particles are induced to partition between the two liquid phases and the interface between them. Particles with similar properties are accumulated in the interface region. The main devices for countercurrent distribution on a laboratory scale using two-phase aqueous systems are the thin-layer and centrifugal countercurrent distribution apparatuses. The viscosity of the phases and long settling times sometimes limits the proper functioning of traditional distribution machines. Countercurrent distribution methods complement more traditional centrifugation techniques for the separation of particles.

## Apparatus

Countercurrent distribution with only a few transfers (up to  $\sim 10$ ) is easily carried out using a set of separating funnels for mixing, settling, and phase transfer. For small phase volumes, 0.5–5 ml, the separating funnels can be replaced by test tubes and the upper phases transferred by pipette. For countercurrent distributions with more than 10 transfers, some kind of automated apparatus is recommended. Some examples of suitable apparatuses are presented below.

### Craig-Type Apparatus

Several different types of countercurrent distribution machines have been constructed for use with organic solvents and water. The most widely known design is the all-glass machine of Craig and Post. Several glass units, allowing mixing, settling, and phase transfers are arranged in batteries on a horizontal axis (Figure 3). Movement about the axis can be used to gently mix the phases, to put the glass units in position for settling of the phases, and for decanting the upper (or lower) phases, respectively. The time for each segment of the operation cycle as well as the number of transfers can be programmed. Standard designs contain from 25 to 250 cells, while more advanced machines with up to 1000 cells have been described. The glass cells are available in various sizes. Standard-size cells have space for  $\sim 2$  ml (fixed amount) of lower phase and up to 5 ml of upper phase.

### Thin-Layer Apparatus

The thin-layer apparatus were developed for use with two-phase aqueous systems for both liquid–liquid

**Figure 3** Section of the Craig-type apparatus for countercurrent distribution. (A) Two segments (or cells) are shown from side and top views. (B) By turning the axis, the upper phases can be decanted. When returning to the original position, the upper phases are transferred to the neighboring cell.

and liquid–interface countercurrent distributions. A drawback of the Craig-type apparatuses for use with two-phase aqueous systems is the long time needed for phase separation to occur, which is a result of the small density difference between phases and their high viscosity. To circumvent this problem Albertsson constructed an apparatus in which the phases form thin layers of  $\sim 2$  mm, thereby reducing the settling time by a factor of  $\sim 10$ . Thin-layer countercurrent distribution takes place in a partition cell block consisting of two cylindrical Plexiglass plates (Figure 4). The lower plate (stator) is fixed while the upper one (rotor) can be rotated stepwise. Both plates have radially oriented cavities, which pair-wise form containers for the two-phase system. The cavities of the stator contain the lower phases

**Figure 4** Thin-layer countercurrent distribution apparatus. The two Plexiglass disks contain matching cavities for the upper and lower phases and by rotation the upper plate can move all upper phases relative to the lower ones.

while the upper phases are situated in the cavities of the rotor and therefore can be transferred relative to the lower phases by rotating the upper plate. The partition block rests on a shaking table, which also contains a drive for the upper plate rotation. The upper cavities are deeper than the lower cavities to allow air space for efficient mixing. A planetary movement of the shaking table achieves mixing of the phase systems. The phase systems are added to each container (chamber) via openings in the upper side of the rotor. These openings, during the run, are covered with a ring-formed lid. All procedures including shaking, settling, and phase transfer are automated by a control unit. After completion of the countercurrent distribution, the two-phase systems are collected by decanting into a fraction collector.

### Centrifugal Apparatus

Akerlund developed a fully automated apparatus utilizing the increased speed of phase separation obtained in a centrifugal field. Instead of using chambers with low height, the time of phase separation is reduced by centrifugation at  $\sim 100g$  after each equilibration step. The operating unit of the machine consists of an outer ring with 60 cavities for the lower phase and an inner plate with corresponding cavities for the upper phase (Figure 5). After mixing, by shaking on a platform in the machine, the plates start to rotate to achieve centrifugal force. While still rotating, the transfers of all the upper phases with respect to the lower phases are carried out by a rotational movement of the inner plate relative to the ring. After the transfer, the centrifugation is stopped and a new cycle begins with the shaking process. After completion of the distribution process, the phases are collected by pipette. With this machine, countercurrent distributions can be carried out with

**Figure 5** Centrifugal countercurrent distribution apparatus. A section of the circular separation unit is shown. It is comprised of four units: c, the outer ring with cavities for the lower phase; d, the inner plate with cavities for the upper phase; e, the lid; and f, an O-ring for sealing. The position of the two-phase system during centrifugation is shown with the upper phase, a, and the lower phase, b. ### Introduction

From simply heating up a meal to preparing a sample for analysis via a multistep process, microwave technology finds various uses in both homes and analytical laboratories. It can help reduce the time taken to complete many processes, and so it is very useful with many types of samples. How microwaves speed up some processes is not fully understood, however. The main factors to be considered here include sample transport properties, molecular agitation, the heating of solvents above their boiling points, and, in some cases, product selectivity.

Analytical chemists began using microwaves in 1975 to digest biological samples. They used domestic microwave ovens then to heat a mixture of a sample and digestion acids rapidly to its atmospheric boiling point in an Erlenmeyer flask. Since this, microwave-assisted methods have been used widely in analytical chemistry. The latest advances in the use of microwaves in various chemical fields include sample digestion for elemental analysis, solvent extraction, sample drying, moisture measurement, analyte adsorption and desorption, cleaning up samples, chromogenic reactions, solid-phase retention, elution, distillation, microwave plasma atomic spectrometry, and synthetic reactions, among others.

Microwave-assisted extraction (MAE) is the process by which microwave energy is used to heat solvents in contact with samples (mainly solid samples) and to partition compounds of interest from the sample into an extractant. Extractions are done in closed or open microwave-transparent vessels where a solvent and sample are combined and then exposed uniformly to microwave energy. Partitioning may occur by any one or several of the following three heating mechanisms: (1) a single solvent or mixture of solvent possessing high dielectric loss coefficients;

(2) solvent mixtures of high and low dielectric loss; and (3) susceptible samples with a high dielectric loss in a solvent of low dielectric loss.

Although the traditional Soxhlet and solvent extraction techniques are widely accepted, they have inherent limitations and problems. Thus, Soxhlet extraction requires 12–24 h in most cases and uses high volumes of organic solvents (hundreds of milliliters). In contrast to conventional methods, MAE can reduce the extraction time to less than 30 min and solvent consumption to under 50 ml. Moreover, the recoveries obtained with MAE are mostly comparable with those provided by alternative methods.

Unlike digestion, MAE is used mainly with soil and sediments rather than with biological samples. As regards analytes, MAE is applied primarily to organic pollutants such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and pesticides rather than to metal species, where other extraction alternatives, such as ultrasound-assisted extraction, are usually more effective.

This article describes the principal applications of microwaves to sample extraction, with special emphasis on solid samples, which have been the most used so far. The description is preceded by a discussion of the equipment used, which can be of the open or closed type, depending on whether they operate at atmospheric pressure or at a higher level and whether they use multimode or focused microwaves. Selected special laboratory designs are also commented on, as is the possibility of coupling of some of these devices to subsequent steps of the analytical process. Before applications are dealt with, the main variables affecting MAE are also examined.

### Microwave-Assisted Extractors

Microwave-assisted extractors can be classified into two groups, according to the way microwave energy is applied to the sample. In multimode systems, the microwave radiation is dispersed randomly in a cavity, and so every zone in the cavity and the sample

### Introduction

From simply heating up a meal to preparing a sample for analysis via a multistep process, microwave technology finds various uses in both homes and analytical laboratories. It can help reduce the time taken to complete many processes, and so it is very useful with many types of samples. How microwaves speed up some processes is not fully understood, however. The main factors to be considered here include sample transport properties, molecular agitation, the heating of solvents above their boiling points, and, in some cases, product selectivity.

Analytical chemists began using microwaves in 1975 to digest biological samples. They used domestic microwave ovens then to heat a mixture of a sample and digestion acids rapidly to its atmospheric boiling point in an Erlenmeyer flask. Since this, microwave-assisted methods have been used widely in analytical chemistry. The latest advances in the use of microwaves in various chemical fields include sample digestion for elemental analysis, solvent extraction, sample drying, moisture measurement, analyte adsorption and desorption, cleaning up samples, chromogenic reactions, solid-phase retention, elution, distillation, microwave plasma atomic spectrometry, and synthetic reactions, among others.

Microwave-assisted extraction (MAE) is the process by which microwave energy is used to heat solvents in contact with samples (mainly solid samples) and to partition compounds of interest from the sample into an extractant. Extractions are done in closed or open microwave-transparent vessels where a solvent and sample are combined and then exposed uniformly to microwave energy. Partitioning may occur by any one or several of the following three heating mechanisms: (1) a single solvent or mixture of solvent possessing high dielectric loss coefficients;

(2) solvent mixtures of high and low dielectric loss; and (3) susceptible samples with a high dielectric loss in a solvent of low dielectric loss.

Although the traditional Soxhlet and solvent extraction techniques are widely accepted, they have inherent limitations and problems. Thus, Soxhlet extraction requires 12–24 h in most cases and uses high volumes of organic solvents (hundreds of milliliters). In contrast to conventional methods, MAE can reduce the extraction time to less than 30 min and solvent consumption to under 50 ml. Moreover, the recoveries obtained with MAE are mostly comparable with those provided by alternative methods.

Unlike digestion, MAE is used mainly with soil and sediments rather than with biological samples. As regards analytes, MAE is applied primarily to organic pollutants such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and pesticides rather than to metal species, where other extraction alternatives, such as ultrasound-assisted extraction, are usually more effective.

This article describes the principal applications of microwaves to sample extraction, with special emphasis on solid samples, which have been the most used so far. The description is preceded by a discussion of the equipment used, which can be of the open or closed type, depending on whether they operate at atmospheric pressure or at a higher level and whether they use multimode or focused microwaves. Selected special laboratory designs are also commented on, as is the possibility of coupling of some of these devices to subsequent steps of the analytical process. Before applications are dealt with, the main variables affecting MAE are also examined.

### Microwave-Assisted Extractors

Microwave-assisted extractors can be classified into two groups, according to the way microwave energy is applied to the sample. In multimode systems, the microwave radiation is dispersed randomly in a cavity, and so every zone in the cavity and the sample

it contains is irradiated. The single-mode or focused system allows focusing of the microwave radiation on a restricted area where the sample is placed for subjection to a much stronger electromagnetic field than in the previous case. **Figure 1** shows a general scheme of both types of extractors. Usually multimode systems (**Figure 1A**) are of the closed-vessel type, where the microwave-assisted treatment is conducted at a high pressure, whereas focused systems (**Figure 1B**) are of the open-vessel type, in which microwaves are applied at atmospheric pressure. This mutual association, however, is incorrect as some devices that operate at a high pressure use focused microwaves, and domestic ovens have been used with multimode sample irradiation but at atmospheric pressure.

Closed-vessel systems have not been used so much for sample extraction as they are primarily used for

sample digestion, whereas the main application of open-vessel systems has been solid sample extraction.

Both multimode and focused microwave devices consist of four major components:

1. The 'magnetron' or microwave generator, where the microwave energy is produced.
2. The waveguide, used to propagate the microwaves from the magnetron to the microwave cavity.
3. The applicator, where the sample is placed. It can be a multimode cavity where microwaves are randomly dispersed or the waveguide itself. In the latter case the sample vessel is placed directly inside to focus the microwave radiation onto the sample.
4. The circulator, which allows microwaves to pass only in the forward direction.

**Figure 1** Scheme of a (A) multi-mode and (B) focused microwave system. (Reproduced with permission from Springer.)

### Closed-Vessel Microwave Systems

The earliest microwave systems for analytical purposes were closed vessels with a multimode cavity. They usually allowed processing of several samples at the same (in a carousel) under pressure and temperature feedback control. Closed vessels exist basically in two different forms. One encompasses noninsulated, relatively thin, single-walled fluoropolymer vessels. These vessels have minimal insulating characteristics and allow large amounts of heat to escape. The other type of closed vessel is a well-insulated container, usually of very thick-walled fluoropolymer, or one with a very thick outer layer or casing (or both). These vessels retain heat very efficiently, and so they do not allow rapid cooling when ambient air is forced over them within the microwave cavity.

Most commercially available closed-vessel microwave systems are based on multimode microwaves; however, the advantages of high-pressure vessels and focused microwave heating have led to the development of systems that combine both assets. These focused high-pressure, high-temperature microwave extractors consist of an integrated closed vessel and a focused microwave-heated system operating at a very high pressure and temperature.

Dynamic systems for high-pressure microwave extraction were developed much later than open-vessel systems because operating under a high pressure reduces the flexibility afforded by working at atmospheric pressure. In 1999, a microwave-assisted flow digestion system was developed from a novel pressure equilibration system that affords temperatures up to 250°C and pressures in the region of 35 bar with previously slurried solid samples. More recently, Ericsson and Colmsjö developed a dynamic high-pressure microwave-assisted extraction device that allows extraction of solid samples, while avoiding the principal drawback of the previous approach (the relative complexity of the assembly and the inability to introduce unslurried solid samples directly).

### Open-Vessel Microwave Systems

The first completely re-engineered laboratory-focused microwave system was introduced by Prolabo in 1986. Most commercial open-vessel microwave systems manufactured since then are of the focused-microwave type, i.e., they use the waveguide as a single-mode cavity. Since their introduction, they have widely been used for sample extraction, substituting in most cases the closed-vessels systems, which as of now are used mainly for carrying out sample digestions.

The principle of focused microwaves is efficient in terms of energy transfer. The electromagnetic energy

and the sample are highly efficiently coupled, and a high density is obtained as a result. In fact, according to Prolabo, the coupling efficiency is increased by a factor of 10 compared with the use of a multimode cavity. Moreover, these open systems allow users to add reagents or fresh solvent during the extraction or to connect a device such as a reflux system. In these open devices, a continuously adjustable percentage of the maximum power is used over a given period of time. This is different from a multimode cavity, where pulsed power is used predominantly. One of the main drawbacks of these designs is that they allow the use of only one flask at a time. Automation in some systems can enable sequential use of flasks. One recent development involves the use of four flasks at a time by splitting the microwave energy symmetrically among the flasks at the end of each waveguide.

As noted earlier, not all open-vessel systems are of the focused type. A number of reported applications used a domestic multimode oven to process the samples for analytical purposes, usually with a view to coupling the MAE to some other step of the analytical process (usually the determination step) as described below.

The increased flexibility of open-vessel systems has promoted the design of new microwave-assisted sample treatment units based on focused or multimode (domestic) ovens adapted to the particular purpose. Regarding MAE, examples of these new units include the microwave-ultrasound combined extractor and the focused microwave-assisted Soxhlet extractor.

The microwave-ultrasound combined system has been constructed from a Prolabo Maxidigest 350 single-mode microwave oven, in which a sonotrode is placed at the base for indirect ultrasonic agitation of the sample. The ultrasonic probe is placed at a sufficient distance from the electromagnetic field to avoid interactions and short-circuits. The use of this system has allowed the digestion of  $\text{Co}_3\text{O}_4$  and olive oil in shorter times than those required by the conventional method (from 3 to 1 h and from 45 to 30 min, respectively).

The focused microwave-assisted Soxhlet extractor design is based on the same principles as a conventional Soxhlet extractor (Figure 2A) modified to facilitate accommodation of the sample cartridge compartment in the irradiation zone of a microwave oven. The latter has also been modified by making an orifice at the bottom of the irradiation zone, thus enabling connection of the cartridge compartment to the distillation flask through a siphon as illustrated in Figure 2B. The use of this device has provided better results than conventional Soxhlet extraction

**Figure 2** (A) Conventional Soxhlet extractor. (B) Focused microwave-assisted Soxhlet extractor from Prolabo. (Reproduced with permission from Ericsson M and Colmsjö A (2000) Dynamic microwave-assisted extraction. *Journal of Chromatography* 897: 279; © Elsevier.)

in much shorter periods of time. It enables focused microwave-assisted Soxhlet extraction (FMASE), retains the advantages of conventional Soxhlet extraction while overcoming restrictions such as a long extraction time, unsuitability for automation, waste of large volumes of organic solvents, and nonquantitative extraction of strongly retained analytes due to the easier cleavage of analyte–matrix bonds by interactions with focused microwave energy, and, unlike a conventional Soxhlet extractor, allows recycling up to 75–85% of the total extractant volume. In addition, solvent distillation in the FMAS extractor is achieved by electrical heating, which is independent of the extractant polarity, thus avoiding the principal problem of commercial focused microwave devices such as those of the Soxwave series from Prolabo.

## Variables Influencing MAE

The performance in microwave-assisted processes depends on a number of variables including the microwave power output, exposure time, solvent used, and sample size used.

### Microwave Power and Exposure Time

The principal variables to be considered in developing an MAE method are the applied power and the irradiation (exposure) time. The power and the corresponding time will depend on the type of sample and solvent used. Usually, these two variables have opposing effects: for a given process, the use of high microwave power affords a decreased exposure time;

on the other hand, the use of low power entails irradiating the sample for a longer time to apply the same amount of energy.

In theory, one should use a high microwave power to reduce the exposure time as much as possible. Occasionally, however, using a very high power is inadvisable; such as in the case of extraction processes, where complete dissolution of the sample should be avoided in order to minimize the effect of potential interference. In some cases, using a very high microwave power decreases the extraction efficiency through degradation of the sample or its analytes or rapid boiling of the solvent in open-vessel systems (which hinders contact with the sample). Sometimes, the application of microwaves over short, intermittent periods results in substantially increased extraction efficiency relative to the continuous application of microwaves, which causes the solvent to boil and hinders sample–extractant contact.

### Temperature and Pressure

Temperature is a key variable in most analytical processes. In MAE, it plays a prominent role and affects the rate of some reactions, the degradation of thermolabile species and the solubilization of some substances, among others. A number of devices have been developed for monitoring or even controlling the temperature.

Pressure is a highly influential factor in closed-vessel systems. The development of vessels capable of withstanding pressures as high as 41 bar has enabled extraction at very high temperatures, thereby increasing dramatically the extraction efficiency and decreasing the exposure time.

### Type of Solvent

The choice of solvent in a microwave-assisted sample treatment is a direct function of the type of treatment used. Thus, digestion and hydrolysis are best done with aqueous solutions of pure or mixed acids, whereas selective extraction of organic compounds from a sample matrix usually requires an organic solvent.

MAE of nonpolar compounds usually entails the adoption of a compromise since, although these compounds are more readily dissolved in nonpolar solvents such as n-hexane, the interaction of microwaves with the solvent depends on its dielectric constant (the greater  $\epsilon$  is, the stronger the interaction); this requires the use of a mixture of solvents of different polarity in many cases. For example, the most suitable solvent for MAE of organic compounds such as PAHs and PCBs is a mixture of hexane and acetone. In specific cases such as in the extraction

of organometal compounds, the use of methanol acidified with acetic acid allows organometals to be extracted in a rapid, efficient manner with no degradation. In some cases such as the extraction of organic compounds of medium or high polarity, pure water can be used as an efficient 'clean' extractant. Although its power of solubility for organic compounds is not as high as those of organic solvents, its interaction with microwaves is much higher due to its high dielectric constant, thus providing high extraction efficiencies and environmentally friendly methods.

### Influence of Sample Viscosity and Sample Size on Microwave Heating

The viscosity of a sample reflects its ability to absorb microwave energy because it affects molecular rotation. The effect of viscosity is best illustrated by considering ice. When water is frozen, the water molecules become locked in a crystal lattice. This restricts molecular mobility greatly and makes it difficult for the molecules to align with the microwave field. Thus, the dielectric dissipation factor of ice is low. When the temperature of the water is increased to 27°C, the viscosity decreases and the dissipation factor rises to a much higher value.

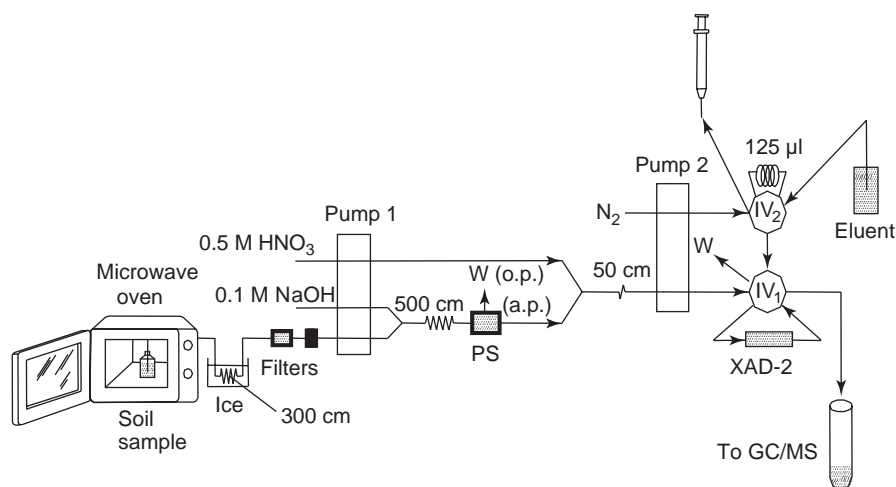

The input microwave frequency also affects the penetration depth of the microwave energy. At a given input frequency, the greater the dissipation factor of a sample is, the less it will be penetrated by microwave energy. In large samples with high dissipation factors, the heating that occurs beyond the penetration depth of the microwave energy is due to

thermal conductance through molecular collisions. Therefore, temperatures at or near the surface will be higher. Because boiling and other agitation increase the rate of thermal conductance, surface heating is not a problem unless penetration is very low and sample heating is extremely superficial. In such a case, heat losses through the vessel walls can be significant and increase the sample heating time.

Although the small sample size used in most analytical dissolution processes has some advantages, it also has at least one disadvantage: the amount of microwave energy absorbed decreases with decreasing sample size. With small sample sizes, a substantial amount of energy is not absorbed but is reflected. Reflected energy can damage the magnetron, and so, in using small samples for analytical work, it is advisable to employ microwave systems designed to protect the magnetron from reflected power.

### Coupling of MAE with Other Operations of the Analytical Process

Online systems using domestic microwave ovens are mainly used for sample digestion. Slurried samples are introduced in a Teflon coil placed in the microwave oven, and after digestion, the solutions are driven to the detector (usually of the atomic type). However, some methods use a domestic microwave oven for extraction purposes, in which the sample is not introduced as a slurry but rather placed in an appropriate vessel that is then introduced into the oven. **Figure 3** shows one of these systems, where the microwave extraction is coupled to subsequent steps

**Figure 3** Experimental design for continuous MAE, liquid-liquid extraction, sorption/cleanup of phenol compounds in soil samples. via a flow injection (FI) manifold, thus providing partial automation of the analytical process.

Commercial focused microwave devices have been used for coupling the extraction with other steps such as filtration, preconcentration, and/or detection. The experimental setup showed in **Figure 4** uses a piston pump as the interface between the extractor and an FI manifold. Extraction is performed by supplying an appropriate extractant in an automatic manner by means of the piston pump. Then, the sample is irradiated with microwaves for a preset time and the extract aspirated through the other pump channel to a vessel connected to the FI manifold, where the analytes are filtered, preconcentrated, and determined chromatographically in an automatic manner.

The dynamic high-pressure MAE system described previously also allows the extraction to be coupled to a subsequent stage by connecting the extractor outlet to the unit concerned. **Figure 5** illustrates one possible coupling: connecting the extractor to a fluorimetric detector allows the kinetics of the extraction of PAHs from sediments to be monitored.

## Applications of MAE

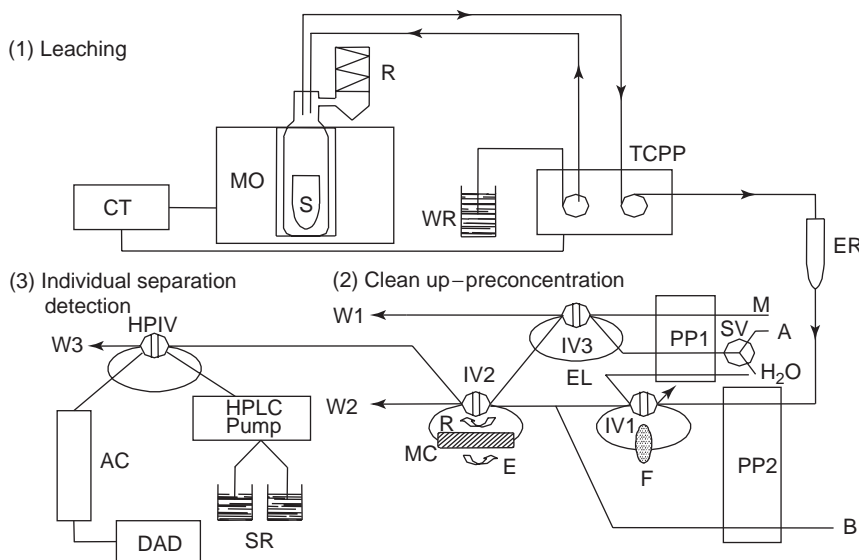

As stated before, MAE has been used mainly for extraction of solid samples. The use of MAE is a continuously expanding area of research at present. As a

result, it is difficult to provide a completely updated overview. Rather, selected groups of compounds of interest that have been subjected to MAE are discussed here.

Traditionally, the extraction of PAHs from solid samples has been conducted using a Soxhlet method, which, while being efficient, usually takes more than 6 h and uses large volumes of solvent. Several reports have indicated that PAHs can be extracted from solid matrices such as soil and plant and animal tissues

relatively easily using MAE. The most effective solution used for leaching PAHs is an acetone–hexane mixture. The use of water as an extractant has also been tested with a view to developing clean methods using no organic solvents. Because of the high hydrophobicity of PAHs, however, the recoveries were very low in spite of the strong interaction between water and microwaves. One way of using water effectively for MAE of nonpolar compounds (PAHs included) is through micelle formation.

Most studies about MAE of PAHs from solid samples have been conducted using closed-vessel systems and only a few with open-vessel focused microwave devices. Because open-vessel systems operate at atmospheric pressure, the extraction vessel has been used as a reactor in order to perform online purification pretreatments of the total extracts (reagents can be added readily to the medium) or introduce the extracts directly into the determination instrument, as in the focused microwave-assisted extractor with online fluorescent monitoring, which provides a matrix-independent approach to the extraction of PAHs.

MAE has also become a frequent choice for the extraction of PCBs from solid matrices. In fact, this technique has been used to extract PCBs from a wide range of samples including soils, sediments, and animal tissues. Normally, the extractant used is the same as that employed with PAHs; micelle formation have also provided results similar to those obtained using conventional methodologies.

A wide variety of pesticides including organochlorine and organophosphorus compounds, triazines, herbicides, and imidazolinones have been extracted using microwaves, with recoveries ~100% in most cases.

Several MAE methods have also been developed for extraction of organometal compounds such as 3-nitro-4-hydroxyphenylarsonic acid and methylmercury from sediments and animal tissues. The MAE recoveries were consistently higher than those achieved with sonication or Soxhlet extraction. All species recoveries were matrix-dependent, as previously found with other pollutants, but using methanol acidified with acetic acid under optimal MAE conditions afforded rapid, efficient extraction of all analytes.

MAE has also been used as a solid sample treatment prior to speciation analysis, leaving the organometal compound moiety intact. This is a prerequisite for a successful extraction procedure to be applied before speciation analysis can be met by careful optimization of the conditions of the microwave attack. Open-vessel treatment is preferred to the pressurized bomb systems commonly used in analysis of total metals because it offers milder reaction conditions (the increase in temperature is governed to a great

extent by the boiling point of the solvent) and easier control of process variables.

Other organic compounds such as phenols, hydrocarbons, polymer additives, and natural compounds have also been extracted from a wide range of samples with good results.

One of the most interesting fields of application of MAE in food analysis is the extraction of lipids. This step, traditionally performed with conventional Soxhlet extraction, has been performed with the focused microwave-assisted Soxhlet extractor prototype of **Figure 2B**. Extraction of oil from olives, sunflower seeds, and soyabeans; extraction of the lipid fraction of dairy products (milk and cheese); and extraction of fatty acids from precooked and sausage foods have significant advantages over conventional methods, including dramatically reduced extraction times, lower degradation of thermolabile analytes, and acceleration of other analytical steps such as hydrolysis in milk samples, in addition to completeness of analyte extraction, which is not always achieved with conventional methods.

The extraction of metals and metalloids has also been assisted by microwaves, most often for speciation analysis. Metals such as Fe, Zn, Cu, As, Se, Hg, Pb, Co, Cr, Ni, and Cd have been extracted using acid solutions (usually  $\text{HNO}_3$ ) in a focused open-vessel system for periods ranging from 3 min for soil samples to 50 min for coal (where the metals are much more strongly retained). MAE has been used both as a pretreatment for chemical speciation (mainly to discriminate As and Se species) and as a means of accelerating fractionation of metals in sewage sludge for operation and/or functional speciation. The former type of application has usually been developed using open-vessel systems coupled to various types of equipment for individual separation and/or determination (e.g., hydride generation–atomic fluorescence detection, electrochemical detection, and liquid chromatography–hydride generation–inductively coupled plasma–mass spectrometry) following extraction.

### Introduction

Over the past few years, a technique based on the use of solvents at a high pressure and high temperature without reaching the critical point has gradually emerged as an efficient means for increasing automatability, shortening process times, and reducing the amount of solvent required to digest or leach solid samples. Such features as the low consumption of organic solvents and the expeditiousness of determinations make this technique especially suitable for environmental analysis, the area where it has expanded to the greatest extent.

The principal aspects of the technique, in its two modes (static and dynamic), the devices typically employed by each, and their amenability to coupling with subsequent operations of the analytical process, which is one of the most interesting aspects of this technique, are discussed in this article. The main variables affecting the extraction process as well as the applications are also commented on.

### Operational Pressurized Fluid Extraction Modes

Depending on the way the sample and extractant are brought into contact, pressurized fluid extraction (PFE) can be implemented in three different operational modes, static, dynamic, and static–dynamic.

In the static extraction mode, the sample is soaked in the extractant and the liquid flow is halted over a preset interval, after which it is propelled to the collection vessel, usually by a nitrogen stream. This extraction mode allows penetration of the extractant, and it is especially useful when the analytes cannot be removed expeditiously from the matrix.

In the dynamic extraction mode, the extractant is pumped through the sample at a preset flow rate. This mode allows the analyte to be exposed continuously to the pure (clean) solvent, thus favoring displacement of the analyte's partitioning equilibrium to the extractant.

Which extraction mode is better remains a controversial issue. The static mode provides longer contact between the sample and solvent, swells the matrix, and facilitates penetration of the extractant in its interstices. However, it is not suitable when the partitioning equilibrium is displaced slightly to the solubilization of the analytes in the extractant. The dynamic mode has the advantage that it puts the sample into contact with fresh extractant continuously but requires a larger amount of extractant and causes dilution of the extracts, which usually calls for a preconcentration step prior to determination of the analytes. The static–dynamic mode, which consists of a combination of the two previous modes, can be used to enjoy the advantages of both modes while circumventing their shortcomings.

### Pressurized Fluid Extractors

PFE has been carried out using both commercial and laboratory-built extractors, depending mainly on the operational mode used. While static PFE is usually carried out using commercial equipment (e.g., Dionex accelerated solvent extraction (ASE) 200 and ASE 300 or, more recently, the one commercialized by Applied Separation), the dynamic mode has been implemented only in laboratory-built extractors as nowadays there is no commercially available equipment. **Figure 1A** and **1B** shows schematic diagrams of a static and dynamic pressurized fluid (PF) extractor, respectively. The former (**Figure 1A**) consists of the following parts: (1) a reservoir for storing the liquid extractant; (2) a high-pressure pump for propelling the extractant through the system; (3) an extraction chamber, consisting of a

### Introduction

Over the past few years, a technique based on the use of solvents at a high pressure and high temperature without reaching the critical point has gradually emerged as an efficient means for increasing automatability, shortening process times, and reducing the amount of solvent required to digest or leach solid samples. Such features as the low consumption of organic solvents and the expeditiousness of determinations make this technique especially suitable for environmental analysis, the area where it has expanded to the greatest extent.

The principal aspects of the technique, in its two modes (static and dynamic), the devices typically employed by each, and their amenability to coupling with subsequent operations of the analytical process, which is one of the most interesting aspects of this technique, are discussed in this article. The main variables affecting the extraction process as well as the applications are also commented on.

### Operational Pressurized Fluid Extraction Modes

Depending on the way the sample and extractant are brought into contact, pressurized fluid extraction (PFE) can be implemented in three different operational modes, static, dynamic, and static–dynamic.

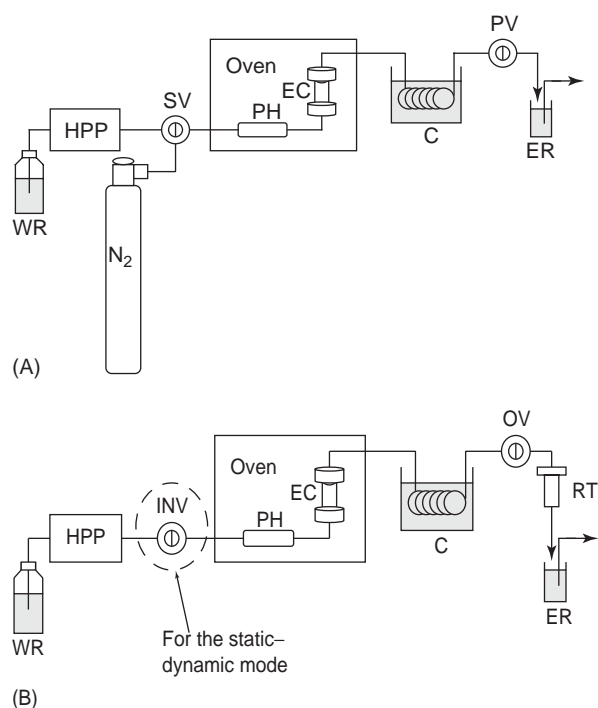

In the static extraction mode, the sample is soaked in the extractant and the liquid flow is halted over a preset interval, after which it is propelled to the collection vessel, usually by a nitrogen stream. This extraction mode allows penetration of the extractant, and it is especially useful when the analytes cannot be removed expeditiously from the matrix.

In the dynamic extraction mode, the extractant is pumped through the sample at a preset flow rate. This mode allows the analyte to be exposed continuously to the pure (clean) solvent, thus favoring displacement of the analyte's partitioning equilibrium to the extractant.

Which extraction mode is better remains a controversial issue. The static mode provides longer contact between the sample and solvent, swells the matrix, and facilitates penetration of the extractant in its interstices. However, it is not suitable when the partitioning equilibrium is displaced slightly to the solubilization of the analytes in the extractant. The dynamic mode has the advantage that it puts the sample into contact with fresh extractant continuously but requires a larger amount of extractant and causes dilution of the extracts, which usually calls for a preconcentration step prior to determination of the analytes. The static–dynamic mode, which consists of a combination of the two previous modes, can be used to enjoy the advantages of both modes while circumventing their shortcomings.

### Pressurized Fluid Extractors

PFE has been carried out using both commercial and laboratory-built extractors, depending mainly on the operational mode used. While static PFE is usually carried out using commercial equipment (e.g., Dionex accelerated solvent extraction (ASE) 200 and ASE 300 or, more recently, the one commercialized by Applied Separation), the dynamic mode has been implemented only in laboratory-built extractors as nowadays there is no commercially available equipment. **Figure 1A** and **1B** shows schematic diagrams of a static and dynamic pressurized fluid (PF) extractor, respectively. The former (**Figure 1A**) consists of the following parts: (1) a reservoir for storing the liquid extractant; (2) a high-pressure pump for propelling the extractant through the system; (3) an extraction chamber, consisting of a

**Figure 1** General setup used to carry out PFE. (A) Static mode and (B) dynamic and static-dynamic modes. WR, water reservoir; HPP, high pressure pump; SV, selection valve; PH, pre-heater; EC, extraction chamber; C, cooler; PV, pressure valve; ER, extract reservoir; INV, inlet valve; RT, restrictor.

stainless steel cylinder closed with screws at either end, which permits circulation of the leaching fluid through the sample; (4) an electrically heated oven for placing the extraction chamber; (5) an on/off pressure valve for producing and keeping an appropriate pressure in the system; (6) a cylinder of gas (usually  $N_2$ ) for purging the system after extraction; (7) a valve located between the high-pressure pump and the oven, which allows flushing the system with the gas; and (8) a collection vessel (usually a vial).

The dynamic pressurized liquid extractor is similar to the static one but with the following modifications, as shown in **Figure 1B**: (1) an outlet valve located outside the oven used to produce the over-pressure required at the beginning of the extraction; (2) a cooler system used to cool the fluid from the oven temperature to  $\sim 25^\circ\text{C}$  (it is usually present in the laboratory-built static PF extractors as well); (3) a restrictor coupled to the outlet of the cooler (substituting the pressure valve) with the aim of maintaining the pressure constant in the system during dynamic extractions; (4) the selecting valve located after the high-pressure pump and the  $N_2$  stream are not present in dynamic extractors as no purging of the system is required in this extraction mode.

**Figure 2** Miniaturized device for dynamic-PFE of solid and semisolid samples. (Reproduced with permission of Elsevier.)

The static-dynamic mode is used with the assembly described for the dynamic mode but including an inlet valve (see INV in **Figure 1B**) for developing the static extraction step prior to the dynamic one. Recently, a laboratory-built miniaturized device for dynamic PFE has been developed (**Figure 2**). The most salient element of this device is a heatable stainless steel holder that serves as the extraction chamber, which is placed between a syringe pump (used to deliver the extractant) and an automated six-port valve for direct control of the pressure inside it.

## Variables Influencing PFE

### Temperature

Temperature is the most important variable affecting the efficiency of mass transfer in PFE as the use of high temperatures increases the extracting power of solvents. A high temperature has a favorable effect, decreasing the viscosity of liquid solvents, thus facilitating penetration of the extractant in the matrix particles. Temperature changes also affect the surface equilibrium. In fact, they alter strong analyte-matrix interactions caused by van der Waals forces, hydrogen bonding, and dipole attractions of the analyte molecules and active sites of the matrix and can lead to disruption of the surface equilibrium in response to positive changes in temperature. Thermal energy can overcome cohesive (analyte-analyte) and

adhesive (analyte–matrix) interactions by decreasing the activation energy required for desorption of the analytes from a solid particle.

Notwithstanding the foregoing, using a high temperature does not always result in increased extraction efficiency. Adverse effects are especially outstanding when thermolabile species are presented.

### Pressure

The pressure is usually a minor variable for the resulting efficiency in PFE, provided the level used is high enough to maintain the solvent in the liquid state. In some cases, however, pressure can be a key to ensuring complete analyte removal. The use of high pressures facilitates extraction from samples where the analytes have been trapped in matrix pores. The pressure increment forces the solvent into areas of the matrices that would not normally be contacted by them under atmospheric conditions.

### Matrix Composition

The composition of the sample (physical–chemical properties, type of compounds it contains, and its particle size) can be an important aspect related to the extraction efficiency. Between these factors the particle size is the most influential. Its influence depends on the particular variable that governs the extraction efficiency. Obviously, if the PFE rate is determined by diffusion of the analytes, it can be increased greatly by decreasing the particle size. However, the risk of losing volatile and reactive analytes during grinding is higher with samples consisting of particles less than 2 mm in size. These two opposing effects must thus be taken into account in reducing the particle size of samples to be extracted.

### Sample Size

Sample sizes for PFE usually range from 0.5 to 10 g. Obviously, the amount of sample used must be large enough to ensure homogeneity and obtain adequate sensitivity for trace analyses. A small sample size (<5 g) is preferred so as to avoid compaction of the sample in the extraction cell. Moreover, the smaller the amount of sample used is, the greater is the cell volume that can be occupied by the extractant and hence the higher is the extractant/analyte ratio and the more markedly shifted is the partitioning equilibrium toward solubilization of the analytes, which facilitates their extraction.

### Solvent Type

Optimal development of an extraction process entails an appropriate choice of solvent. The PFE technique is compatible with a wide range of solvents

other than those with an auto-ignition temperature of 40–200°C (e.g., carbon disulfide, diethyl ether, 1,4-dioxane) or a strong polar character. As a rule, strong bases and acids should also be avoided as solvents because they are corrosive, and their corrosion power increases with increasing pressure and temperature. The PFE technique provides an opportunity for the use of a variety of solvents or solvent mixtures, even those that are not effective in conventional methods. This is done by adjusting the temperature and pressure during the process, which generally increases the solubilization power of the solvents.

The static mode uses both organic solvents such as toluene, methanol, and acetone and solvent mixtures (usually in a 1:1 ratio) including dichloromethane–acetone, acetone–hexane, heptane–acetone, acetone–isohexane, and methanol–water. Water has rarely been used as the extractant in the static mode; however, it is the extractant most frequently used in the dynamic mode, both alone and with modifiers such as organic solvents, surfactants, and derivatizing reagents.

### Solvent Volume

The amount of solvent required depends strongly on the extraction mode used. In the static mode, the sample is extracted with a minimum volume of solvent (usually <15 ml), with no outflow. When the solvent volume used in the static mode does not ensure quantitative extraction of the target analytes, several extraction cycles or the dynamic mode must be used. In the dynamic mode, the extractant flows continuously through the extraction cell, and so the volume of solvent that comes into contact with the sample is a direct function of both the flow rate of the circulating extractant and the extraction time. Obviously, the dynamic mode uses larger volumes of solvent than the static mode, and so it is less well suited for trace analysis, although there are various ways of minimizing this dilution effect, as shown below.

### Solvent Flow Rate

This is a characteristic variable of the dynamic extraction mode. The effect of the flow rate on the efficiency and expeditiousness of PFE can be used to determine whether the extraction is limited by analyte solubility in the extractant, diffusion in the particles, and/or transfer from the particle surface to the extractant. If the extraction efficiencies do not change when the flow rate is increased, then the extraction is limited neither by the solubility nor by the equilibrium of mass transfer between the matrix and extractant, and so the rate-determining step of the

process is diffusion inside the solid particles. In such a case, the extraction rate must be increased by raising the extraction temperature. If the limiting factor is analyte solubility, then doubling the flow rate doubles the amount of analyte that is extracted during the same time. On the other hand, if the analyte undergoes different readsorption/desorption steps during elution from the extraction chamber, doubling the flow rate also doubles the extraction rate.

### **Extraction Time**

Extraction times in PFE are very short relative to those required by conventional solid-liquid extraction techniques such as Soxhlet extraction and depend on which particular process determines the extraction rate. The extraction times in PFE usually range between 5 and 30 min, but they can be as long as 90 min in highly unfavorable cases such as the extraction of selenium, mercury, and arsenic from coal.

### **Coupling PFE with Other Steps of the Analytical Process**

One of the most interesting aspects of this technique (apart from the good results it provides) is the possibility of coupling to other steps of the analytical process, thus enabling partial or total automation of the analytical process and solving problems such as dilution of the extracts when the dynamic extraction mode is used, the lack of selectivity under the extraction conditions, or the presence of solid suspended particles in the extracts.

#### **Coupling Static PFE Mode**

Static pressurized liquid extraction, as implemented in commercial equipment, is basically discrete in nature, and so it is rarely coupled to other operations of the analytical process. In fact, only in a few reported applications is the static mode coupled online to other operations such as chromatographic separation, preconcentration, and detection. In any case, custom extractors are used as the compact design of the commercial models precludes their adaptation.

Static PFE has been coupled to solid-phase extraction (SPE) with both SPE disks placed directly into the extraction chamber jointly with the sample and by using a minicolumn packed with the sorbent material and connected at the end of the extractor by means of a flow injection manifold. The minicolumn can be placed either in the transport tube or in the loop of an auxiliary injection valve of a flow-injection manifold, thus enabling elution in the direction opposite to retention. Analytes can be eluted manually, by disconnecting the column from the extractor, or

automatically (either by passing a volume of organic solvent with the aid of a pump and collecting the eluate, which is made to volume in a vial, or by using a second injection valve to control the eluted volume, thus ensuring reproducibility). The latter mode also has the possibility of direct transfer of the eluate to a liquid or gas chromatograph also in an automatic manner. In both modes, the solid phase must be allowed to dry before the analytes are eluted; to this end, an air or nitrogen stream is passed after the extract has been passed through the column.

A laboratory-made static PF extractor has also been coupled to a high-performance liquid chromatograph directly with the aim of passing the extract through the analytical column in an automatic manner after static extraction. This coupling has been performed by just connecting the injection valve of the liquid chromatograph to the outlet tube of the extractor, thus allowing injection of a fraction of the extract.

The coupling of a static PF extractor to a fluorimeter has been performed primarily to develop an independent matrix extraction method allowing the extraction kinetics to be monitored. This approach has been followed with a view to determining the number of static extraction cycles required for quantitative extraction of the analytes, irrespective of the kind of matrix concerned and whether the species concentrations in it were known. The extract obtained after each cycle is driven to a graduated reservoir from which it is aspirated into a flow-injection manifold connected to the fluorimeter.

#### **Coupling Dynamic PFE**

The potential of the dynamic PFE technique for coupling to subsequent operations of the analytical process is only limited by the analyst's ingenuity and material resources. The systems described below can be combined by altering the sequence of steps and introducing appropriate modifications to develop fully automated systems for specific purposes.

Two different approaches to the liquid-liquid extraction of leached analytes have been reported. One, which is discrete in nature, uses a vial containing the immiscible organic solvent, through which the aqueous leached phase is percolated. The other operates in a continuous manner, by percolating the effluent from a restrictor through a flow cell located at the detector and filled with an organic phase that is lighter than water and allows partitioning of the extracted analytes into the organic solvent. In the latter case, by dissolving an appropriate complexing agent in the organic phase, it has been possible to monitor indirectly the extraction kinetics.

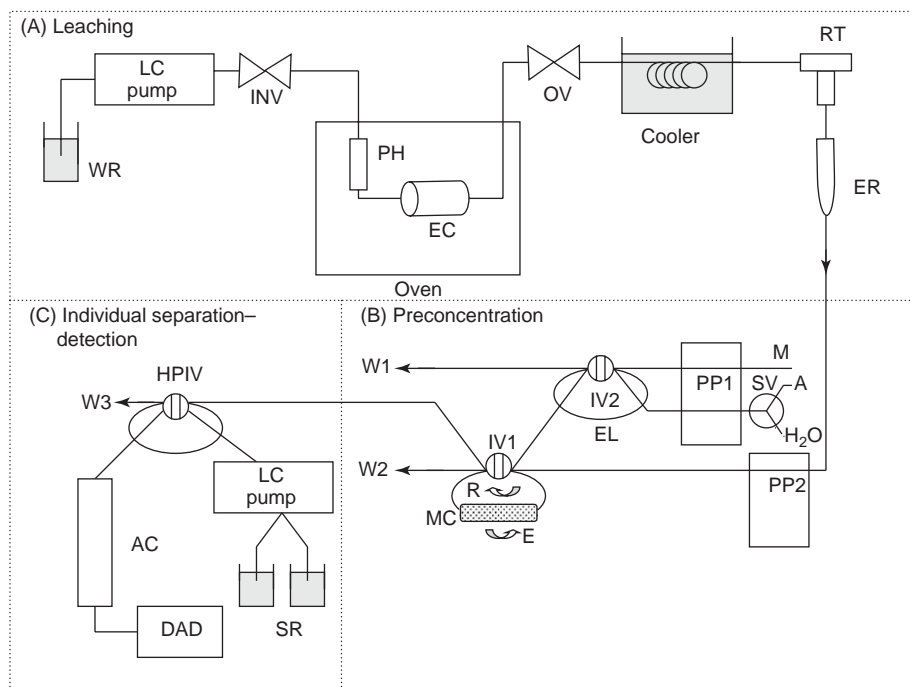

Dynamic PFE usually requires implementing a concentration step prior to the determinative step, and because the extracted analytes are dissolved in a liquid (usually aqueous) phase, SPE is a highly useful tool for avoiding the dilution effect. For this purpose, SPE cartridges and columns packed with appropriate sorbents and coupled online to the extractor outlet can be employed in the same way as commented on for static PFE. Miniaturized retention has also been developed by using solid-phase microextraction (SPME).

One very common, undesirable occurrence in dynamic PFE is the presence of solid particles in the liquid extract due to oversaturation during cooling. This shortcoming can be circumvented by fitting a filtration unit in line with the extractor. The unit can be placed either in the transport tube or in the loop of an auxiliary injection valve; the latter choice allows the filter to be cleaned between samples by passing a rinsing solution at a high flow rate in the direction opposite to filtration.

When the extracted analytes provide no response on passing through a flow cell located in a detector connected online to the continuous extractor via a dynamic manifold, the extractor outlet can also be connected to a manifold where the extract is merged with a stream of an appropriate reagent to derivatize the analytes as they are extracted, thereby enabling their subsequent online determination.

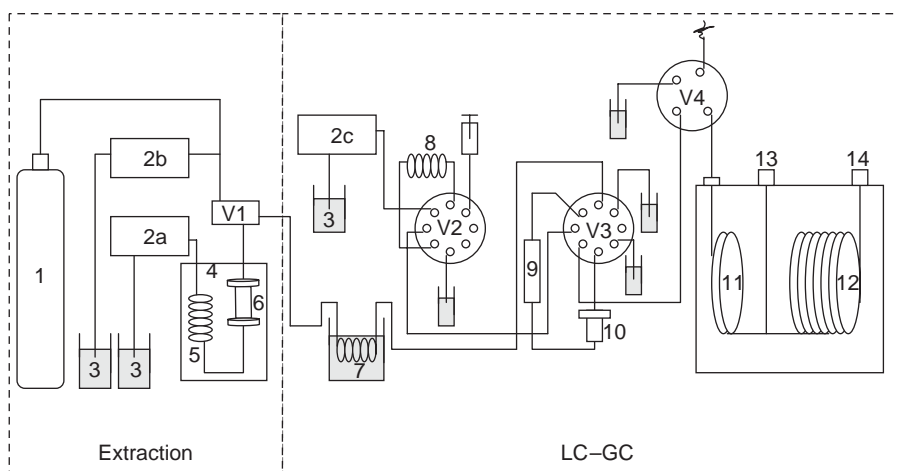

Coupling of dynamic PFE with supercritical water oxidation has been carried out in order to oxidize (destroy) organic compounds previously extracted using PFE such as polyaromatic hydrocarbons (PAHs), phenol, and benzaldehyde, among others, as a way of treating waste. Two ovens, one containing the extraction vessel and another containing the reaction tube, are connected by a tube that is insulated. Two high-pressure pumps are used, one to deliver the extractant (water) to the extraction vessel and another to deliver the oxidant (hydrogen peroxide) to the stream at a T confluence in the second oven.

The dynamic PFE–SPE–liquid chromatography (LC) coupling has been implemented with two different configurations. In one, the chromatographic mobile phase also acts as the eluent for the analytes retained on the SPE column; in the other, elution is done by using an injection valve that allows the eluent volume to be controlled in a reproducible manner. In the latter configuration (Figure 3), the eluate is swept to the high-pressure injection valve in the chromatograph using air as carrier to avoid dilution. In both assemblies, the SPE column is placed in the loop of a six-way valve to allow continuous passage of the mobile phase through the chromatographic column and detector in order to establish the baseline. Also, in the latter, elution is done in the direction opposite to

retention to avoid changes in compaction of the sorbent material.

PFE has been combined directly with a liquid chromatography-gas chromatography (LC-GC) system. **Figure 4** shows the experimental setup used. The analytical procedure developed with this system is divided into five steps: (1) PF extraction. The sample is extracted and the analytes are trapped in the Tenax column. After extraction, the water flow is stopped by closing valve V1 and pump 2a. (2) Drying. After extraction the column is dried with nitrogen to remove water. The nitrogen flows through valve V1. (3) LC clean-up. Valve V3 is switched, and pump 2c pushes the eluent (pentane) through the column. After this, the eluent is changed to pentane/ethyl acetate, which is delivered from the loop by switching valve 2. (4) Transfer to GC. When the fraction containing the analytes is eluted from the Tenax column, valve V4 is switched, and the fraction is transferred to GC. During the transfer, partially concurrent solvent evaporation is applied. (5) After transfer, the tubing attached to the extraction vessel and the trap column is flushed. After rinsing the lines and column, they are dried with a flow of nitrogen. The next extraction can then be started while the GC analysis of the previous extraction is still proceeding. The main benefit of this coupling is that the concentration step is highly efficient, so that the sensitivity is ~800 times better than that obtained with traditional methods.

Sorbent materials can also be used in the flow cell of a nondestructive detector for continuous monitoring of the retention step, thus providing an indirect way of controlling the extraction kinetics. The

kinetics can be monitored in a direct manner if the analytes possess appropriate intrinsic properties or follow online derivatization. In both cases, completion of extraction is shown by the obtainment of a plateau (a constant signal) as a result of the constancy in the analyte content on the solid support. Once the signal levels off, the analytes can be eluted to waste – thus making the manifold ready for processing a new extract – or a portion of the extract can be inserted into a gas or liquid chromatograph for its individual determination as the sorbent is regenerated for a new extraction.

## Applications of PFE

PFE has so far been applied exclusively to solid samples, especially in environmental analysis, which accounts for over 80% of its reported uses. In recent years, however, PFE has been used increasingly in the pharmaceutical and industrial fields as well (especially for extraction of additives from polymers).

Soil and sediments constitute the principal environmental target samples, and organic pollutants, the main target analytes. Static and dynamic PFE modes have been used for the extraction of PAHs, polychlorinated biphenyls, phenols, chlorophenols, hydrocarbons such as diesel range organics, waste oil organics, surfactants, etc., as well as inorganic compounds such as those of phosphorus, heavy metals, and organometals. As commented before, organic solvents have been used mainly in the static mode; meanwhile, water has been used in the dynamic one both alone and with some modifiers

such as organic solvents, derivatization agents, and surfactants. In most of the cases, the results obtained have been comparable with those obtained using other techniques such as Soxhlet extraction, supercritical fluid extraction, and microwave-assisted extraction.

PFE has been used in the analysis of biological samples for two main purposes, namely to determine contaminants in food and animal tissues and to extract target species from animal and plant tissues. In the last case, dynamic-PFE has been used widely for isolation of edible essential oils from plants such as fennel, marjoram, laurel, rosemary, oregano, and eucalyptus, using water as the extractant.

In the pharmaceutical field, PFE has also been used for two primary purposes, namely to extract pharmacologically active substances from plants and, especially, for quality control of tablets and medical foods. In this field, PFE clearly surpasses classical extraction methods such as those endorsed by pharmacopeias (which use as official standards techniques such as Soxhlet extraction, percolation, maceration, digestion, extraction under reflux, and steam distillation) and others based on ultrasonication or turboextraction. PFE is a firm candidate for use in high-throughput screening programs for natural product discovery, where large numbers of small-scale extractions have to be performed in an efficient, reproducible manner.

PFE has been used to extract various additives from different types of polymers, all with good results and the intrinsic advantages of this technique, which include a high throughput, solvent economy, and the production of extracts that require no

filtration. Thus, PFE has enabled the efficient extraction of flame-retarded thermoplastic additives, plasticizers such as dioctyl adipate, trioctyl phosphate, dioctyl phthalate, and trioctyl trimellitate, and antioxidants such as Irganix and Irgafos from various polymers including poly(vinyl chloride), polyethylene, and polypropylene.

## Introduction

Supercritical fluid extraction (SFE) is today an important technique for the extraction of a large number of differing analytes from various matrices such as pollutants from soils, fats from food stuffs, active substances from plants, and additives from polymers. The obtained extracts are normally analyzed on a chromatographic system even though other

techniques are applied (e.g., gravimetry and spectroscopy). Compared to many methods based on conventional liquid extraction, SFE offers speed and cleaner extracts, decreasing the need for external clean-up steps. This cuts the total costs of analysis due to reduced labor-intensiveness. There is also an environmental advantage, as harmless extraction fluids are normally used. This is important as regulations are getting stricter on the use of certain chlorinated organic solvents, with increasing costs for solvent disposal. The reason for the decreased interest in SFE, starting at the end of the last decade, was mainly caused by an initial over enthusiasm in SFE, when first introduced in the mid-1980s. In some early attempts, SFE was also applied on analytes and matrices for which it was not well suited.

such as organic solvents, derivatization agents, and surfactants. In most of the cases, the results obtained have been comparable with those obtained using other techniques such as Soxhlet extraction, supercritical fluid extraction, and microwave-assisted extraction.

## Supercritical Fluid Extraction

**E Björklund and C Sparr-Eskilsson**, Lund University, Lund, Sweden

© 2005, Elsevier Ltd. All Rights Reserved.

This article is a revision of the previous-edition article by A A Clifford, pp. 4724–4725, © 1995, Elsevier Ltd.

## Introduction

Supercritical fluid extraction (SFE) is today an important technique for the extraction of a large number of differing analytes from various matrices such as pollutants from soils, fats from food stuffs, active substances from plants, and additives from polymers. The obtained extracts are normally analyzed on a chromatographic system even though other

techniques are applied (e.g., gravimetry and spectroscopy). Compared to many methods based on conventional liquid extraction, SFE offers speed and cleaner extracts, decreasing the need for external clean-up steps. This cuts the total costs of analysis due to reduced labor-intensiveness. There is also an environmental advantage, as harmless extraction fluids are normally used. This is important as regulations are getting stricter on the use of certain chlorinated organic solvents, with increasing costs for solvent disposal. The reason for the decreased interest in SFE, starting at the end of the last decade, was mainly caused by an initial over enthusiasm in SFE, when first introduced in the mid-1980s. In some early attempts, SFE was also applied on analytes and matrices for which it was not well suited.

Additionally, unsatisfactory extraction efficiencies were often blamed on poor extraction conditions, while the true cause was inadequate collection. Consequently many laboratories regarded SFE as too complex and abandoned the technique despite its excellent features. However, at present there are many well-conducted scientific applications and comprehensive text books that aids in the development of potent and competitive methods for the replacement of many conventional liquid-based methods such as Soxhlet. The basic concepts of SFE and important factors governing the extraction process will be outlined. Several applications suitable for SFE will also be presented.

## **Alternative Extraction Techniques**

SFE is today not the only hyphenated extraction technique available. Both microwave-assisted solvent extraction (MAE) and pressurized fluid extraction (PFE) have evolved in parallel with SFE during the last decade. A thorough comparison of the different techniques can be found in the analytical literature, and will assist in choosing an appropriate technique for a specific application. These newer techniques offer both speed and simplicity, while some of the main benefits of SFE are still inherent to the usage of supercritical fluids as MAE and PFE utilize liquid solvents. More recently, subcritical water extraction has also been introduced as an environmental friendly alternative but the reader is referred to the analytical literature on this research topic.

## **Coupling of SFE to Other Techniques**

There are a number of online methods coupling SFE to other analytical techniques such as gas chromatography (GC), capillary or packed column supercritical fluid chromatography (SFC), and liquid chromatography (LC). The online techniques are rather sensitive because the entire portion of extracted components is transferred to the column. A disadvantage with online approaches is that coextracted fat, water, and sometimes modifier may interfere in the final analysis. Additionally overloading of the analytical column must be avoided. Therefore, only small samples are usually extracted with online methods in SFE. A comprehensive discussion of online methods can be found in Further Reading.

## **Supercritical Fluids**

A supercritical fluid refers to a substance above its critical temperature ( $T_c$ ) and pressure ( $p_c$ ), where

only fluids exist, and the distinction between gases and liquids disappear. As the pressure is increased the fluid changes from being gas-like to become liquid-like in its properties. Compared to liquids, diffusion is faster and viscosity is lower, which results in a more rapid matrix penetration and analyte transport out of the sample. Surface tension is also low resulting in a good matrix wetting. The density of a supercritical fluid is close to a liquid and can be adjusted by simply changing the pressure. This compressibility of supercritical fluids allows the density, and thereby, the solvent strength at a given temperature, to be easily adjusted, and admits some selectivity to the extraction. Solvent strength is often expressed (qualitatively) using the Hildebrand solubility parameter ( $\delta$ ) and allows for some comparison between supercritical fluids and liquid solvents. However,  $\delta$  is not always sufficient to describe a supercritical fluid, since other physicochemical properties of the molecule might affect the extraction efficiency, such as permanent dipole moments. It is also important to point out a major misconception that density alone governs analyte solubility. Temperature also plays an important role and often increases analyte solubility for certain compounds (see the section 'Solubility, temperature, and pressure'). In fact the simplest way to describe extraction conditions is to give information on pressure and temperature, as these define the density of the supercritical fluid. Additionally, most instruments require that pressure and temperature are set prior to starting the extraction.

Even though the extraction efficiency for some analytes can be increased by change of extraction fluid, carbon dioxide is by far the most common compound used (98% of all applications). It has low critical parameters, it is nonexplosive, nontoxic, and environmentally benign. Alternatives have been proposed such as alkanes and freons but they have never been widely accepted due to health and safety risks for the former and ozone depletion by the latter. One of the few competitors to carbon dioxide is nitrous oxide, however, it might cause explosion in contact with high amounts of organic material. Supercritical carbon dioxide has a polarity similar to that of n-hexane, and consequently for the extraction of more polar analytes an organic modifier such as methanol or acetonitrile (1–5%) has to be added to increase the polarity (see the section 'Modifiers'). To maintain supercriticality for two-component fluids, somewhat different conditions have to be applied, but normally there is no problem at the conditions under which SFE is normally carried out.

## Instrumentation

### Basic SFE Setup

A simplified picture of an instrumental SFE setup is shown in Figure 1.

The SFE instrument consists of a solvent supply, a pump to maintain the pressure and the flow rate, an extraction cell mounted in a heated oven in order to maintain the temperature at the specified value, a restrictor connected to the outlet of the cell, and a collection device. There are different ways of collecting analytes as discussed in the section 'Collection Devices'. In a representative experiment, the cell has a volume of  $\sim 10$  ml and is loaded with 1–5 g of sample matrix. Carbon dioxide is pumped at a rate of  $0.5\text{--}4\text{ ml min}^{-1}$ , measured as liquid at the pump. The pressure is 150–450 bar and the temperature  $40\text{--}150^\circ\text{C}$ , with a dynamic extraction time of 10–60 min. The extracting fluid is transported through a restrictor. At the restrictor, the pressure of the extracting fluid drops as the extraction fluid expands, releasing the extracted compounds. The gaseous extraction fluid is vented and the analytes are collected in a small volume of solvent (5–20 ml) or onto a solid-phase trap (commonly octadecyl-silica), which is rinsed with solvent in a subsequent step. The extract is often ready for direct analysis. An internal standard is added to the vial to correct for differences in final extract volumes.

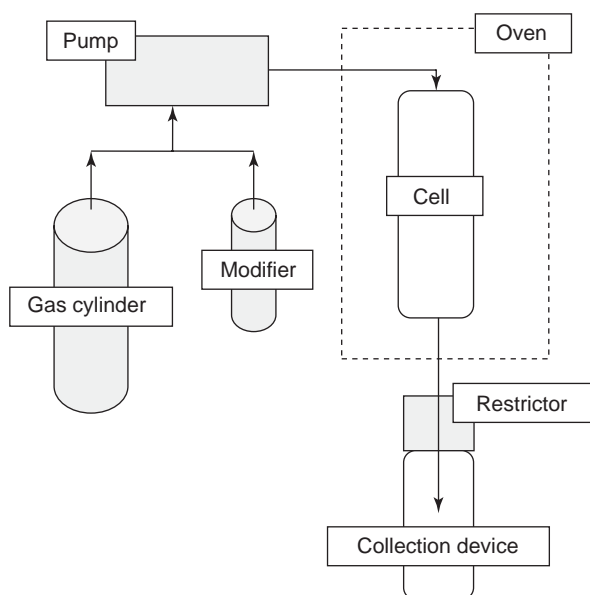

In certain applications, static extractions can be performed. In the static mode, the outlet valve is closed, the cell filled with fluid, and the inlet valve is closed. The fluid is then left in contact with the

matrix for 10–30 min. The valves are opened and the fluid in the cell is swept into the analyte trap by performing a dynamic extraction. Static extraction is less common than dynamic extraction, but has been considered preferable for some applications. When the extraction process is controlled by a slow removal of analytes out of the matrix into the extracting fluid (see the section 'Analyte/matrix considerations and sample types'), an initial static extraction step may be advantageous. A combination of such a static and dynamic step then usually leads to higher recoveries in a shorter time than using a single dynamic step.

### Equipment Items

**Pumps and fluid supply** For analytical SFE, two pumps types are common: syringe pumps and reciprocating pumps. Conventional LC pumps can also be used for SFE. Though syringe pumps are generally reliable with a limited need of maintenance, a disadvantage is the limited capacity and need of refilling regularly. A suitable SFE pump should measure both pressure and flow rate. Additionally, the maximum pressure (at least 400 bar) should be maintained at the maximum flow rate required (at least  $4\text{ ml min}^{-1}$ ). Moreover, the set pressure should be reached fast when the inlet valve to the extraction cell is opened. It is also important that the pump is sufficiently cooled. Cooling can be performed by water or by using an additional carbon dioxide cylinder for this purpose. The fluid substance is contained in a cylinder with a dip-tube and used so that liquid is supplied to the pump. Also available are gases, which have an overpressure of helium of  $\sim 100$  bar, which removes the necessity of cooling the pump. Unfortunately carbon dioxide supplied in this way contains  $\sim 3\%$  of helium, and studies have shown that these cylinders preferably should be avoided. They are also relatively expensive.

LC-grade solvents are normally used as modifiers. The modifier can be added directly into the extraction cell prior to extraction. In this case no additional pump is needed. A disadvantage is that the entire volume of modifier is extracted together with the analytes during the dynamic mode of the extraction. Using premixed cylinders is another option. A range of mixtures of carbon dioxide with various modifiers added (1–10%) are commercially available. There are severe drawbacks of premixed cylinders as there is less flexibility in the choice of the solvent used, and the composition of the liquid supplied from mixed cylinders changes over the lifetime of the gas mixture. The most convenient and most commonly preferred way is the use of an additional LC pump for

**Figure 1** Schematic apparatus for carrying out SFE.

modifier delivery. When using a gradient LC pump in automated SFE systems, several modifiers with different concentrations can easily be tested.

**Extraction cells** Different cell types are available, but the best choice is cells that can be sealed properly without any tools. In commercial systems hand-tightened extraction cells are standard. Cells are available in sizes from 1 to 100 ml. The material in the cells should be inert and should not absorb the extracting media. Stainless steel or crystalline polymers are common materials for this purpose. There have been discussions on the orientation of the extraction cells, but the most logical way is a vertical position with the fluid entering from the top. This means that there is no delay in emergence of the extracted analytes. Solid matrices should be uniformly packed into the cell, with no easy passages for the fluid. Care must be taken when assembling the cell to keep particles away from the surfaces of the connectors.

**Restrictors** Several different types of restrictors have been used in analytical SFE. The simplest method of providing pressure or flow control is to use a tubing of fused silica capillary as a linear restrictor. Tubing of 20–30  $\mu\text{m}$  internal diameter and lengths of 10–50 cm are usual. One major drawback with linear restrictors may be blockage caused by coextraction of matrix components, i.e., water, sulfur, lipids, waxes, and small particles. Water gives rise to plugging by freezing in the outlet caused by cooling due to the expansion of the fluid and the evaporation of the

trapping solvent. To avoid the problem with clogging, the restrictor can be heated and/or some kind of water-adsorbing material is mixed with or placed downstream the sample. Blockage may also be avoided by heating the solvent collection vial, taking care not to evaporate the trapping solvent, which can lead to loss of volatile analytes. The advantage of the fused silica restrictor is the low cost. However, care must be taken in order to obtain reproducible results when complex samples are extracted. Alternatively, linear restrictor can be made of stainless steel or inert polymeric materials.

In a needle valve restrictor, the flow rate is controlled by changing the valve position. This can be performed during the extraction to avoid blockage. The drawbacks with needle valves are virtually the same as for capillary restrictors. The preferred choice is electrically controlled restrictors, which maintains a back-pressure or flow rate set by the operator. These devices are not very often subject to blockage, which makes them highly reliable and often form part of commercial SFE instrument. Two types of restrictor designs are shown in **Figure 2**.

A coaxial heated restrictor consisting of a syringe with a movable piston position controls the flow, or alternatively a small metal disk is pushed toward an orifice in order to regulate the flow rate. The former is suitable for collection in organic solvents, while the latter has been utilized for solid-phase trapping.

**Collection devices** The importance of a proper collection of analytes in SFE has been emphasized by

**Figure 2** Two types of restrictors, combined with organic solvent collection or solid-phase trapping. (A) Solvent collection; (B) solid-phase trapping.

numerous investigations. Faulty collection rather than nonquantitative extraction could explain low extraction recoveries. Collection in a solvent is most commonly achieved by keeping the restrictor outlet immersed into a vessel containing a small volume of an organic solvent (Figure 2A). There are several parameters to consider, including solvent type, solvent volume, solvent temperature, restrictor flow rate, restrictor temperature, and pressurization of the collection vessel. Solvent collection is rather insensitive to analyte breakthrough losses when the sample contains large amounts of fat or water that can be coextracted, or when a modifier is used. However, volatile analytes are more difficult to trap in a solvent than on an adsorbing solid-phase trap.

In solid-phase trapping, the decompressed extraction fluid passes a device filled with a sorbent material (e.g., chromatographic material such as octadecylsilica, diol, silica, and Florisil<sup>®</sup>, Figure 2B). After extraction is completed, the analytes are eluted from the solid-phase trap with a suitable solvent. The choice of trapping material (single or a combination of adsorbents), trapping temperature, and the eluting solvent or solvent mixture is of great concern. The capacity of the trapping material may be a limiting factor, resulting in breakthrough losses of analytes. Even if the target analytes do not exceed the limit of the trap, losses may occur because of overloading of the trapping material with coextracted matrix components. However, one way of avoiding capacity problems is to perform a fractionated extraction/elution procedure, i.e., to rinse the trap at certain time intervals during the extraction. There is a major drawback when using solid-phase trapping together with water-containing samples or when high concentrations of modifier are added to the extraction fluid. During these conditions condensation of water or modifier in the trap may cause breakthrough losses of analytes. A common solution is to keep the trapping temperature above the boiling point of the modifier. Collection with the use of an adsorbent has the potential for selective trapping. Compared to solvent collection, the solid-phase trapping technique offers high trapping efficiency for substances with high vapor pressures since the trap temperature can easily be reduced to  $-30^{\circ}\text{C}$ . Collection in an empty vessel has also been employed in analytical-scale SFE, mostly for fat extractions, even though it may result in lower recoveries compared to collection in a vessel containing solvent.

### Commercial Equipment

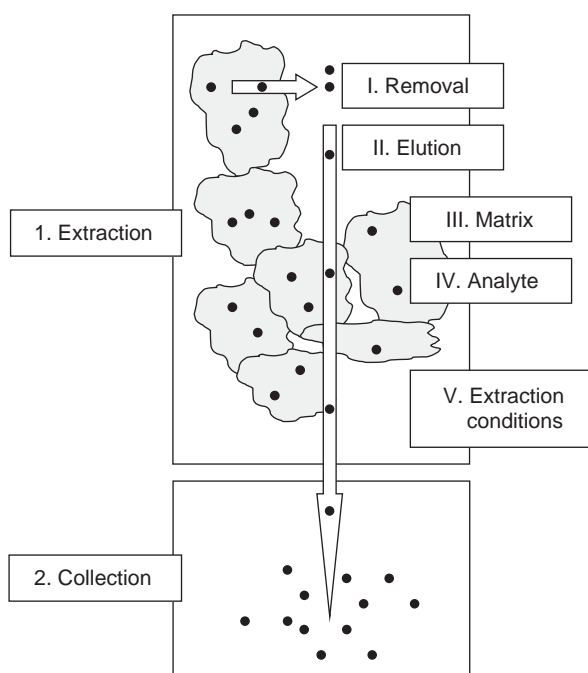

A number of companies produce SFE equipment offering convenience and easy control of extraction

conditions. Other features are simultaneous extraction of samples (2–4) or sequential sample extraction (8–24) as well as direct extraction of liquid samples. In the last few years, smaller lab/pilot-scale extraction units, specialized for certain applications have entered the market. These are designed for the extraction of oils and aroma compounds from natural products, active components from pharmaceuticals, polymer fractionation, and precision parts cleaning. Some of these are also utilizable in the analytical laboratory. Certain devices offer a phase monitor for visual observation of materials under conditions that may be controlled by the researcher. Thereby, the solubility parameters of compounds and mixtures in subcritical and supercritical fluids can be determined.

### Factors Affecting SFE

The basic requirement for SFE to be useful is that it should be quantitative. Consequently, reliable methods must be developed based on good understanding of the extraction process. In principle, an extraction method consists of an extraction step (1) and a collection step (2), both equally important (Figure 3).

The collection step is often overlooked but it is the first thing to be evaluated in a new method. Secondly, the extraction step must be considered, since several factors influence analyte recovery. Much is still unknown about the precise mechanisms involved in the

**Figure 3** Major factors affecting the overall SFE process. See text for detailed discussion of the various factors.

extraction process (which applies to all extraction methods) but in principle the analyte must be removed from the matrix (I) followed by elution of the analyte from the extraction cell (II), where both matrix and analyte characteristics (III, IV) will influence the extraction process (Figure 3). Consequently the extraction conditions (V) have to be optimized to obtain a quantitative extraction within a reasonable time.

### **Collection Step**

The evaluation of the collection step requires that the analyte is spiked on an inert matrix such as stainless steel beads or sand, and that preliminary extraction conditions are chosen. If low recoveries are achieved it is either caused by insufficient solubility of analytes (often nonvolatiles) or poor trapping conditions (normally volatiles or semivolatiles). This is conveniently verified by reextraction of the residual with an organic solvent to check the presence of remaining analytes in the extraction cell. Once the collection has been set, the extraction step can be evaluated in more detail. Modest solubility of the analyte in the fluid is often sufficient for eluting the analytes from the extraction cell, and consequently for matrices where mild conditions can be applied, the collection step is rather uncomplicated. However, for certain analyte/matrix combinations stronger conditions are needed, and when major changes are made to the initial mild conditions (e.g., rise in temperature or modifier addition), the collection step must be verified once more.

### **Extraction Step**

**Analyte removal** For analyte removal to be successful, the applied extraction conditions must be strong enough to overcome analyte/matrix interactions such as adsorption of analytes on active surfaces, and speed up transport processes of analytes within the matrix. Often an increase in temperature or addition of a modifier significantly improves these processes. Analyte transport may be normal diffusion of the solute or may involve diffusion of the analyte through the fluid along pores in the matrix. Adsorption and desorption may take place during transport, but often the precise process will not be known even though a transport process similar to diffusion occurs.

**Analyte elution** The solubility of the analyte is the main factor controlling analyte elution, and to be successful the analyte must be sufficiently soluble in the fluid. Analytes with low affection for the matrix and with high solubility are eluted fast. There are different ways of increasing the solubility to achieve

a satisfying transport out of the cell such as decreasing or increasing the temperature and increasing the pressure. Also the addition of modifier may drastically increase solubility, but changes to these factors will also affect the initial removal of analytes from the matrix.

**Analyte/matrix considerations and sample types** Since both the transport of analytes from the matrix to the bulk fluid (removal) and the transport of analytes from the extraction cell to the collection device (elution) govern the extraction process, but to different extents for different analyte/matrix combinations, attempts have been made to classify samples. Two extreme groups of sample types can be identified based on flow rate studies; those where the analytes are recovered at a rate proportional to the fluid flow through the extraction cell, and those completely unaffected by the flow rate. In the former group of samples, the elution of the analytes is controlling the extraction speed, while in the latter group of samples, analyte removal is limiting the overall extraction procedure.

In general, samples controlled by the elution process contain high amounts of weakly bound analytes such as oil in oil seeds or bulk fat in pig meat. These samples will gain from increased flow rates and extraction times. Small sample sizes are preferable as is dynamic extraction processes. It is also important to increase analyte solubility. Samples controlled by the removal process often contain trace levels of very hardly bound analytes such as pesticides in soils or flame retardants in sediments. This group of sample will be relatively unaffected by flow rate and extraction time. Sample size is of less importance, and static extraction steps are often as efficient as dynamic. It is, however, important that the cell void volume is satisfactorily swept by the dynamic step. For these sample types, the most important thing to consider is the analyte/matrix interactions and to find ways to break these. This above description is of course a rough simplification. There are examples of fat components present at bulk levels in fishes that are hard to extract, just as there are soil and sediment samples containing trace levels of organic contaminants that are relatively easy to extract. Moreover, sample classification gives some insight into the various problems encountered for different sample types and the reader is referred to the Further Reading section for a more thorough discussion on sample classification and extraction behavior.

**Solubility, temperature, and pressure** Solubility depends not only on the nature of the fluid and its density, but also on the temperature. At a given temperature an increase in pressure will cause an

increase in density and therefore normally an increase in solubility. However, at a constant pressure an increase in temperature will cause a decrease in density, but not necessarily a decrease in solubility. For analytes with relatively high vapor pressures, the drop in density at increased temperatures is by far outweighed by solubility increases caused by vapor pressure effects at higher temperatures. Only compounds with insignificant vapor pressures will suffer from decreased densities at increased temperatures. A more detailed discussion on this topic can be found in the Further Reading section.

Depending on the type of application different combinations of pressure and temperature must be considered. For matrices where analyte elution from the cell is the main controlling factor, an increase in pressure might lead to faster extractions, as more analytes can be dissolved in the fluid when density is increased. However, for other matrices where the transport from the matrix to the bulk fluid is the critical factor, the temperature is often a better parameter to speed up the extraction as it will affect both desorption and diffusion processes. Care must, however, be taken when increasing the temperature so that thermal degradation of heat sensitive analytes is avoided.

**Modifiers** In some cases, the solvent strength of the supercritical fluid (e.g., carbon dioxide) is too low and, therefore, a modifier (e.g., methanol) can be added. The modifier will then cause increased solubility of more polar analytes. For example, carbon dioxide does not extract phospholipids to a very great extent, but by adding 5–10% methanol to the fluid, quantitative recoveries can easily be achieved. In this case the modifier is improving the transportation of the analyte out of the cell (elution). However, modifiers may also assist in the breaking of strong analyte/matrix interactions for certain applications, thereby, improving the transportation of the analyte from the matrix to the bulk fluid (removal). In these cases the analytes are normally sufficiently soluble in the fluid even without modifier present, and therefore, the main role of the modifier is to interact with certain regions of the matrix to which the analytes are bound by specific bonds. The nature of these interactions is often not known and various modifiers with differing chemical characteristics should preferably be tested. Once an appropriate modifier has been identified it can normally be added in relatively small concentrations (1–2%). It is, however, crucial to understand that the addition of modifiers will cause an increased coelution of unwanted matrix components. Additionally the collection efficiencies might decrease dramatically unless

analyte trapping is evaluated separately with these new experimental settings. Especially solid-phase trapping can suffer from severe analyte losses by modifier condensation in the trap. This can often easily be avoided by increasing the trap temperature.

## Sample Pretreatment

Normally solid samples are extracted and it is important to grind them in order to obtain homogeneity. Grinding can conveniently be performed with a mortar and pestle or a kitchen blender. Grinding often facilitates the extraction process, but in certain cases grinding might negatively influence the extraction. There is always a risk of losing analytes on the surface device or by evaporation, and carry-over effects must also be eliminated. Another important factor to consider is the water fraction of the sample. In some applications for more polar analytes, water might act as a modifier, but generally large amounts of water hinder the extraction process. It is common to handle the water fraction by mixing with an adsorbent such as sodium sulfate or Hydromatrix. Another option is freeze drying, but with a risk of losing volatiles. The analyst should consult the analytical chemical literature for specific applications as well as the Further Reading section for a more in-depth discussion of sample pretreatment.

## Verifying a Final Method

Once a method has been developed including a quantitative collection step combined with an exhaustive extraction process, it is necessary to test the method's wider applicability. This is unfortunately a critical step (and applies to all extraction techniques) since it is impossible to know the total amount of a certain analyte present in a real-world sample. There are certain strategies that should be adopted to verify the quantitateness of the method. The applied extraction conditions can be altered by increasing the temperature for matrices known to bind analytes hard or increase pressure for matrices known to contain bulk levels of analytes. If this improves extraction recoveries, the method is not final. Another important option is to compare SFE recoveries with recoveries obtained with conventional extraction procedures (Soxhlet) or other modern extraction techniques (PFE). If the same results are achieved, it is likely that the developed method is quantitative. It is also possible to reextract the SFE residual with another extraction method, thereby, detecting remaining analyte residues in the matrix. A third alternative is to utilize certified reference materials where

**Table 1** Examples of the use of SFE in sample preparation

Matrices	Examples of analytes extracted
Soils, sediments, sewage sludge, fly-ash	Polychlorinated biphenyls, polycyclic aromatic hydrocarbons, dioxins, phenols, pesticides, metals
Foods	Fats, drugs, additives, pesticides, dioxins, mycotoxins, vitamins
Biological fluids/tissues	Drugs, steroids, narcotics, polychlorinated biphenyls, polycyclic aromatic hydrocarbons, dioxins, metals
Polymers, food packaging, cosmetics	Low oligomers, surfactants, additives
Plant material	Essential oils, bioactive compounds, flavors, fragrances, pesticides, metals
Water samples, beverages	Phenols, metals, polycyclic aromatic hydrocarbons, alcohols, flavors, fragrances, bioactive compounds

concentrations have been independently determined by several laboratories.

## Applications

When considering SFE for a specific application, a literature search is always necessary. SFE has been successfully carried out on a wide variety of matrices as seen in **Table 1**. There are also reference methods available for certain applications, for example, the US Environmental Protection Agency (EPA) methods for extracting various pollutants from solid environmental matrices (EPA method 3560, 3561, and 3562). Many SFE manufacturers also provide their customers with application notes focused on specific analytes and matrices. Useful information can also be found in the Further Reading section.

## Solid-Phase Extraction

J S Fritz, Iowa State University, Ames, IA, USA

## Introduction

Despite highly selective and sensitive instrumentation for quantitative chemical analysis, a preliminary

sample preparation step often is necessary for sample cleanup or to isolate components of interest from a sample matrix. In the past, liquid–liquid extraction (LLE) has played a major role in sample preparation. However, recovery of sample components by liquid extraction tends to be slow and labor intensive. The disposal of organic solvents used in liquid extraction is an environmental concern.

In solid-phase extraction (SPE), solutes are extracted from a liquid phase into a solid phase. Most commonly, the liquid phase is a predominately aqueous sample solution and the extractive solid phase consists of small porous particles of silica with a bonded organic outer layer or else it is an organic polymer, such as cross-linked polystyrene. The extraction can take place in a batch mode in which the solid extractant particles are intimately mixed with the sample and then filtered off. However, in chemical analysis it is more common to use a flow-through mode in which the liquid sample is passed through a bed of the solid extractant packed in a small tube. This technique gives more complete extraction of the desired analytes than the batch mode, in which there is only a single equilibration of analytes between the liquid and solid phases.

Substances that have been extracted by the solid particles can be removed by washing with an appropriate liquid solvent. For example, most organic analytes are eluted from an SPE tube (column) with an organic solvent such as acetone, acetonitrile, or methanol. Usually, the volume of solvent needed for complete elution of the analytes is much smaller than the original sample volume. An increased concentration of the analytes is thus achieved.

Extracted molecules can often be removed from solid particles by heating in a gentle stream of a non-reactive carrier gas. This is a convenient way to transfer the molecules into a gas chromatograph for analysis.

In some respects the mechanism of SPE is similar to that of LLE where an extractive organic solvent is added to the aqueous sample solution and the vessel is agitated vigorously to create a temporary emulsion. The emulsion consists of very small spherical solvent droplets suspended in the aqueous phase. The interfacial contact area between the two phases must be quite large in order to promote rapid mass transfer of the analytes from the aqueous to the organic phase. To complete the desired extraction, a finite amount of time is required for the emulsion to break and the phases coalesce into separate layers. The lower layer is carefully drawn off to complete the separation.

In SPE, the solid particles must be small (typically 10–50  $\mu\text{m}$  in diameter) and porous with a large surface area (often 200–800  $\text{m}^2\text{g}^{-1}$ ) to provide an intimate interfacial contact for fast, efficient mass

transfer. A major attribute of SPE is that excellent contact is accomplished simply by allowing the liquid sample to flow through a bed of spherical solid particles contained in a tube or membrane.

The advantages of solid-phase extraction over conventional LLE are:

1. Faster, with less manipulation. A sample can be quickly passed through an SPE column or cartridge by means of a pump or with gentle pressure or suction. After a quick rinse, the extracted substances can be washed from the column by a small volume of an organic solvent or another appropriate eluent. These steps can be automated readily. By contrast, simple solvent extraction requires a considerable amount of manipulation in adding the extractive liquid, shaking, waiting for the emulsion to break, and carefully separating the two liquid phases.
2. Much smaller amounts of liquid organic solvents are used. The large quantities of organic solvents used in analytical separations have become an environmental concern. Aqueous samples become contaminated with organic solvents and evaporative concentration of the extracts pollutes the air with organic vapors.
3. Less stringent requirements for separation. SPE is a multistage separation method and as such requires only a reasonable difference in extractability to separate two solutes. Separation of two solutes by LLE requires complete extraction of one solute in a single equilibration and essentially zero extraction of the other.
4. Higher concentration factors. The concentration factor tells how many times more concentrated a substance is in the extract than it is in the original sample. In SPE, concentration factors of 1000 or more are possible.

## SPE Particles

Bonded-phase silica materials are the most widely used particles for SPE. Since the technology of bonded-phase silica packings for LC columns was already well developed, it was relatively easy for suppliers to offer similar materials in a form suitable for SPE. The most common types are listed in **Table 1**. Octadecylsilane, or sometimes octylsilane, particles are used for retention of relatively hydrophobic organic analytes from predominately aqueous samples. A more polar particle, such as cyanopropylsilane, is selected for SPE of less hydrophobic analytes. Cation- and anion-exchange resins are used in small precolumns to concentrate sample ions from very dilute aqueous samples prior to their

**Table 1** Bonded-phase silica particles for SPE, listed in approximate order of increasing polarity

Phase	Designation
Octadecyl	C18
Octyl	C8
Cyclohexyl	CH
Phenyl	PH

Carboxymethyl	CBA, Weak cation exchanger
Aminopropyl	NH <sub>2</sub> , Weak anion exchanger
Propylbenzene sulfonic acid	SCX, Strong cation exchanger
Trimethylaminopropyl	SAX, Strong anion exchanger

determination by ion chromatography. Cations, such as protonated amine analytes, are retained with some selectivity by particles with a strong- or weak-acid functional group. Anionic analytes are taken up by a material with amino or quaternary ammonium groups.

Excellent polymeric particles for SPE are now available commercially. Most of these are cross-linked polystyrene materials, but some polymethacrylate particles are also available. Organic polymers are more stable than silica materials at alkaline pH values and also tend to have a larger surface area, which enhances their extractive ability. Introduction of  $-\text{CH}_2\text{OH}$  or  $-\text{COCH}_3$  groups into polystyrene resins enhances their ability to extract more polar organic analytes, and also improves mass transport of analytes from the aqueous to the solid phase. A co-polymer of divinylbenzene and vinylpyrrolidone, known as 'Oasis', is also well suited for SPE of relatively polar analytes.

Restricted access polymers are finding extensive use in clinical analysis. Large biomolecules pass quickly through a small column while smaller organic solutes are retained and concentrated by SPE.

Various activated carbon sorbents were used extensively in the early days of SPE. Although activated carbon has very strong sorptive ability, subsequent elution of analytes is often kinetically slow and incomplete. Nowadays, porous graphitic carbon particles are available that work very well for SPE, especially for phenolic compounds that are poorly retained by other sorbents.

A class of compounds known as molecular sieves has found numerous uses in chemical analysis. Molecular sieves are silica or metal-silica particles that contain cavities that are usually 5–6 Å in diameter. Compounds small enough to enter the cavities are sorbed by the molecular sieve while larger molecules are excluded. Virtually all molecular sieves are hydrophilic. However, a molecular sieve known as Silicalite has the rather unique property of being

**Table 2** Recovery of organic analytes by SPE on a Silicalite column

Class	Compound	Recovery (%)
Aldehydes	<i>trans</i> -Crotonaldehyde	91

hydrophobic, at least within the cavities of the sieve. Silicalite is commercially available from UOP and has been used very successfully in SPE to retain small, polar organic analytes. Even ethanol and propanol are retained to some extent. Percentage recoveries of several test compounds by SPE on a short Silicalite column and subsequent elution are given in **Table 2**.

Of the many sorbents available for SPE of organic solutes from predominately aqueous samples, bonded-phase silica particles are undoubtedly the most widely used. But are they best? The relative extractive abilities of the various solid-phase extractants can perhaps best be compared by measuring the retention factors ( $k$ ) with analytes of different chemical structure. Because  $k$  values are often too high to measure readily in water alone, they can be measured in a series of methanol–water solutions and the value in water alone ( $k_w$ ) obtained by linear extrapolation. The values of  $k_w$  for some representative solutes are compared in **Table 3** for C18 silica, a cross-linked polystyrene polymer (PRP-1), and pyrolytic graphitized carbon (PGC). These and other results reveal that polystyrene particles give higher  $k_w$  values than C18 silica in virtually every case. PGC gives lower values than polystyrene sorbents for most organic solutes except for some polyhydroxy compounds.

**Table 3** Comparison of  $k_w$  values with C18 silica, PRP-1, and PGC sorbents

Solute	$k_w$ value		
	C18 silica	PRP-1	PGC
Acetophenone	63	1250	—
Aniline	12	200	22
Benzene	160	3300	28
Benzoic acid	80	2000	250
1,4-Dihydroxybenzene	—	7	140
Phenol	35	250	63
Toluene	560	14 000	—

## Steps in a Solid-Phase Extraction

In its simplest form, SPE can be carried out in a small column packed with a short bed of solid extractive particles (see **Figure 1**). Commercial cartridges are very popular for SPE. Typical cartridges contain ~300, 600, or 900 mg of packed bed. As a general guideline, cartridges can extract up to ~1 mg of sample components per 100 mg of packing.

The SPE process can be divided into four main steps:

1. **Conditioning.** Without some pretreatment an aqueous sample will flow in small channels through the hydrophobic solid phase without making good interfacial contact. Conditioning the column with a little organic solvent such as methanol before introduction of the sample will largely avoid this difficulty.
2. **Adsorption.** The liquid sample is passed at a reasonably constant rate through the column with the aid of suction, applied pressure, or a pump. Columns or cartridges packed with 50–100  $\mu\text{m}$  particles generally necessitate the use of a resin bed 50 mm or more in length. Columns packed with smaller particles are more efficient and can be used with a shorter packing bed.
3. **Washing.** When the sample has passed through the column, a small volume of a wash liquid is used to remove the remaining, unextracted sample. Water, or water containing a low percentage of an organic solvent, is a typical wash solution.
4. **Elution.** In the elution step the adsorbed analytes are removed from the solid extractant and are returned to a liquid phase that is suitable for analytical measurement. Most commonly, the eluting phase is an organic liquid, although it is often possible to thermally desorb analytes with the aid of a gas stream.

The eluting solvent must be compatible with the analytical measurement methods to be used. For

**Figure 1** A simple SPE column.

example, when gas chromatography is to be used, the eluting solvent should have a fairly low boiling point so that the large solvent peak will not interfere with the sample peaks. The eluting solvent should be mostly free from impurities that might give interfering chromatographic peaks.

Many different organic solvents and mixtures of solvents have been proposed for elution of organic analytes in SPE. A study of the elution of aromatic analytes (benzene, naphthalene, anthracene, and chrysene) showed methanol and acetonitrile to be inefficient eluents. The best solvents for these aromatics were tetrahydrofuran and ethyl acetate. Methylene chloride was also very effective but formed an immiscible layer with the residual water in the column.

## Formats

Packed cartridges and mini-columns are often used for SPE. A typical cartridge includes a plastic or glass tube with porous metal or plastic frits at both ends. It is filled with 100–500 mg of 40  $\mu\text{m}$  particles. Although SPE cartridges are popular and easy to use, the relatively large particle size of the sorbent and mediocre packing efficiency necessitate the use of a relatively slow flow.

In 1989, a new family of sorbents for SPE was introduced by the 3 M Company under the trade name Empore. The sorbent particles are a nonspherical bonded-phase silica or a porous poly(styrene-DVB) held together by PTFE fibrils. Approximately 90% of the weight of the membrane is made up of the sorbent particles. The particles are close together in the membrane but not necessarily touching one another. The resin-impregnated membranes are flexible and generally are ~0.5 mm thick.

Sample solutions flow evenly through the thin ( $\sim 0.5$  mm thick) membrane making intimate contact with the extractive particles. It would be very difficult to avoid uneven flow (channeling) through a 0.5 mm bed of loose particles packed into a SPE tube. Studies with very dilute solutions of a dye show that the dye is taken up by the uppermost part of the membrane and that the dye uptake is very even over the entire area of the circular disk. Owing to the small volume and extraction efficiency of the membrane disk, elution of retained analytes requires a much smaller volume of eluting solvent than SPE cartridges.

In laboratories that have a large number of samples to analyze, some degree of automation has become essential. SPE is amenable to automation and is used widely for sample pretreatment. A popular system consists of an array of extraction plates with wells that hold 96 collection tubes, usually in rows of eight tubes each. An assembly of eight automatic pipettes applies samples to the system one row at a time. Semiautomatic elution is also employed. With this system the time needed to process 96 samples is reduced to  $< 1$  h.

### Introduction

Solid-phase microextraction (SPME) was developed to address the need to facilitate rapid sample preparation both in the laboratory and onsite where the investigated system is located. In this technique, a small amount of extracting phase dispersed on a solid support is exposed to the sample for a well-defined period of time. In one approach, a partitioning equilibrium between the sample matrix and extraction phase is reached. In this case, convection conditions do not affect the amount extracted. In the second approach utilizing short time pre-equilibrium extraction, if convection/agitation is constant, the amount of analyte extracted is related to extraction time. Quantification can then be performed based on timed

accumulation of analytes in the coating. **Figure 1** illustrates several implementations of SPME that have been considered. They include primarily open bed extraction concepts such as coated fibers, vessels, agitation mechanism disks, but in-tube approaches are also considered. Some implementations better address issues associated with agitation while other

**Figure 1** Configurations of solid-phase microextraction.

Sample solutions flow evenly through the thin ( $\sim 0.5$  mm thick) membrane making intimate contact with the extractive particles. It would be very difficult to avoid uneven flow (channeling) through a 0.5 mm bed of loose particles packed into a SPE tube. Studies with very dilute solutions of a dye show that the dye is taken up by the uppermost part of the membrane and that the dye uptake is very even over the entire area of the circular disk. Owing to the small volume and extraction efficiency of the membrane disk, elution of retained analytes requires a much smaller volume of eluting solvent than SPE cartridges.

In laboratories that have a large number of samples to analyze, some degree of automation has become essential. SPE is amenable to automation and is used widely for sample pretreatment. A popular system consists of an array of extraction plates with wells that hold 96 collection tubes, usually in rows of eight tubes each. An assembly of eight automatic pipettes applies samples to the system one row at a time. Semiautomatic elution is also employed. With this system the time needed to process 96 samples is reduced to  $< 1$  h.

### Introduction

Solid-phase microextraction (SPME) was developed to address the need to facilitate rapid sample preparation both in the laboratory and onsite where the investigated system is located. In this technique, a small amount of extracting phase dispersed on a solid support is exposed to the sample for a well-defined period of time. In one approach, a partitioning equilibrium between the sample matrix and extraction phase is reached. In this case, convection conditions do not affect the amount extracted. In the second approach utilizing short time pre-equilibrium extraction, if convection/agitation is constant, the amount of analyte extracted is related to extraction time. Quantification can then be performed based on timed

accumulation of analytes in the coating. **Figure 1** illustrates several implementations of SPME that have been considered. They include primarily open bed extraction concepts such as coated fibers, vessels, agitation mechanism disks, but in-tube approaches are also considered. Some implementations better address issues associated with agitation while other

**Figure 1** Configurations of solid-phase microextraction.

implementations address sample introduction into the analytical instrument. It should be noted that SPME was originally named after the first experiment using an SPME device that involved extraction onto solid fused silica fibers contained in a syringe needle. However, the term SPME broadly defines the appearance of the small amount of the solidified extraction phase, frequently involving polymers relative to a liquid or gaseous donor phase (matrix), even though it is recognized that the polymeric extraction phase is not always technically a solid (for example, polydimethylsiloxane). In this article, the principles of SPME and the theoretical aspects of SPME method optimization will be discussed.

SPME has been introduced as a modern alternative to traditional sample preparation technology and it is able to address many of the requirements put forward by analytical researchers. This technique eliminates the use of organic solvents, substantially shortens analysis time and allows for convenient automation of the sample preparation step. SPME can integrate sampling with sample preparation, making it suitable for onsite analysis and process monitoring. The configurations and operation of the SPME devices are very simple. The technology is designed to greatly simplify sample preparation. This feature, however, creates a false impression that the extraction is a simple, almost trivial process. This misunderstanding frequently results in disappointments. It should be emphasized that the fundamental processes involved in SPME are similar to more traditional techniques and therefore challenges to develop successful methods are analogous. The nature of target analytes and complexity of sample matrix determine the level of difficulties in accomplishing a successful extraction. The simplicity, speed, and convenience of the extraction devices primarily impacts the costs of practical implementation and automation of the developed methods.

## Principles of Solid-Phase Microextraction

In SPME, a small amount of extracting phase associated with a solid support is placed in contact with the sample matrix for a predetermined amount of time. If the time is long enough, a concentration equilibrium is established between the sample matrix and the extraction phase. When equilibrium conditions are reached, exposing the fiber for a longer time does not accumulate more analytes. Two different implementations of the SPME technique have been explored extensively to date. One is associated with a tube design and the other with a fiber design. The tube design can use very similar arrangements as

solid-phase extraction, but the primary difference, in addition to volume of the extracting phase, is that the objective of SPME is never an exhaustive extraction. This substantially simplifies the design of systems. For example, in-tube SPME for liquid analysis uses 0.25 mm ID tubes and  $\sim 0.1 \mu\text{L}$  of extraction phase as related to breakthrough is not relevant as exhaustive extraction is not an objective. In fact, the objective of the experiment is to produce full breakthrough as soon as possible as this indicates equilibrium extraction has been reached.

A more traditional approach to SPME involves the use of coated fibers. The first commercially available SPME fiber device is shown in Figure 2. The transport of analytes from the matrix into the coating begins as soon as the coated fiber has been placed in contact with the sample (Figure 3). Typically, SPME extraction is considered to be complete when the analyte concentration has reached distribution equilibrium between the sample matrix and the fiber coating. In practice, this means that once equilibrium is reached, the extracted amount is constant within

**Figure 2** Design of the first commercial SPME device made by Supelco.

**Figure 3** Microextraction with SPME.  $V_f$ , volume of fiber coating;  $K_{fs}$ , fiber/sample partition coefficient;  $V_s$ , volume of sample;  $C_0$ , initial concentration of analyte in the sample.

the limits of experimental error and it is independent of further increase of extraction time. The equilibrium conditions can be described as:

$$n = \frac{K_{fs} V_f V_s C_0}{K_{fs} V_f + V_s} \quad [1]$$

where  $n$  is the number of moles extracted by the coating,  $K_{fs}$  is a fiber coating/sample matrix distribution constant,  $V_f$  is the fiber coating volume,  $V_s$  is the sample volume, and  $C_0$  is the initial concentration of a given analyte in the sample.

Strictly speaking, this discussion is limited to partitioning equilibrium involving liquid polymeric phases such as polydimethylsiloxane. The method of analysis for solid sorbent coatings is analogous for low analyte concentration, since the total surface area available for adsorption is proportional to the coating volume if constant porosity of the sorbent is assumed. For high analyte concentrations, saturation of the surface can occur, resulting in nonlinear isotherms. Similarly, high concentration of a competitive interference compounds can displace the target analyte from the surface of the sorbent. Equation [1], which assumes that the sample matrix can be represented as a single homogeneous phase and that no headspace is present in the system, can be modified to account for the existence of other components in the matrix by considering the volumes of the individual phases and the appropriate distribution constants. The extraction can be interrupted and the fiber analyzed prior to equilibrium. However, in order to obtain reproducible data, constant convection conditions and careful timing of the extraction are necessary.

Simplicity and convenience of operation make SPME a superior alternative to more established techniques in a number of applications. In some cases, the technique facilitates unique investigations. Equation [1] indicates that, after equilibrium has been reached, there is a direct proportional relationship between sample concentration and the amount of analyte extracted. This is the basis for analyte quantification. The most visible advantages of SPME exist at the extremes of sample volumes. Because the setup is small and convenient, coated fibers can be used to extract analytes from very small samples. For example, SPME devices are used to probe for substances emitted by a single flower bulb during its life span. The use of submicrometer diameter fibers permits the investigation of single cells. Since SPME does not extract target analytes exhaustively, its presence in a living system should not result in significant disturbance. In addition, SPME facilitates speciation in natural systems since the presence of a minute fiber, which removes small amounts of analyte, is not likely to disturb chemical equilibria in the system. It should

be noted that the fraction of analyte extracted increases as the ratio of coating to sample volume increases. Complete extraction can be achieved for small sample volumes when distribution constants are reasonably high. This observation can be used to advantage if exhaustive extraction is required as it is very difficult to work with small sample volumes using conventional sample preparation techniques. SPME also allows rapid extraction and transfer to an analytical instrument. SPME can be used for studies of the distribution of analytes in a complex multiphase system and speciate different forms of analytes in a sample. These features result in an additional advantage when investigating intermediates in the system.

In addition, when the sample volume is very large, eqn [1] can be simplified to:

$$n = K_{fs} V_f C_0 \quad [2]$$

which points to the usefulness of the technique for field applications. In this equation, the amount of extracted analyte is independent of the volume of the sample. In practice, there is no need to collect a defined sample prior to analysis as the fiber can be exposed directly to the ambient air, water, production stream, etc. The amount of extracted analyte will correspond directly to its concentration in the matrix without being dependent on the sample volume. When the sampling step is eliminated, the whole analytical process can be accelerated and errors associated with analyte losses through decomposition or adsorption on the sampling container walls will be prevented.

### Extraction Modes with Coated Fiber

Three basic types of extractions can be performed using SPME: direct extraction, headspace configuration, and a membrane protection approach. **Figure 4** illustrates the differences among these modes. In the direct extraction mode (**Figure 4A**), the coated fiber is inserted into the sample and the analytes are transported directly from the sample matrix to the extracting phase. To facilitate rapid extraction, some level of agitation is required to transport analytes from the bulk of the solution to the vicinity of the fiber. For gaseous samples, natural convection of air is sufficient to facilitate rapid equilibration. For aqueous matrices, more efficient agitation techniques, such as fast sample flow, rapid fiber or vial movement, stirring, or sonication is required. These conditions are necessary to reduce the effect caused by the 'depletion zone' produced close to the fiber as a result of fluid shielding and slow diffusion coefficients of analytes in liquid matrices.

**Figure 4** Modes of SPME operation: (A) direct extraction, (B) headspace SPME, and (C) membrane-protected SPME.

In the headspace mode, the analytes need to be transported through the air barrier before they can reach the coating. This modification serves primarily to protect the fiber coating from damage by high molecular mass and other nonvolatile interferences present in the sample matrix, such as humic materials or proteins. The headspace mode also allows modification of the matrix, such as a change of the pH, without damaging the fiber. Amounts of analyte extracted from the same vial at equilibrium into the coating using direct and headspace sampling are identical as long as sample and gaseous headspace volumes are the same. This is due to the fact that the equilibrium concentration is independent of fiber location in the sample/headspace system. If the above condition is not satisfied for very volatile analytes, a significant difference in sensitivity will be observed between the direct and headspace methods.

The choice of sampling mode has a significant impact on extraction kinetics. When the fiber coating is in the headspace, the analytes are removed from the headspace first, followed by indirect extraction from the matrix as shown in **Figure 4B**. Overall mass transfer to the fiber is typically limited by mass transfer rates from the sample to the headspace. Therefore, volatile analytes are extracted faster than semivolatiles since they are at a higher concentration in the headspace and contribute to faster mass transport rates through the headspace. Temperature has a significant effect on the kinetics of the process by determining the vapor pressure of analytes. In fact, the equilibration times for volatiles are shorter in the headspace SPME mode than for direct extraction under similar agitation conditions. This outcome is produced by two factors: a substantial portion of the analyte is in the headspace prior to extraction and diffusion coefficients in the gaseous phase are typically four orders of magnitude larger than in liquid media. As concentrations of semivolatiles in the gaseous phase at room temperature are typically small, overall mass transfer rates are substantially lower

and result in longer extraction times. Extraction times can be improved by using very efficient agitation or by increasing the extraction temperature.

The effect of elevated sampling temperature is a lowering of fiber sample partition coefficients. This decreases the amount extracted at equilibrium but it may be acceptable if target limits of detection can still be reached. This effect is demonstrated dramatically with the analysis of amphetamines. At room-temperature extraction, a very long equilibrium extraction time is observed, but ultimately the highest amount was extracted. Conversely, the highest temperature tested (73°C) produced a very short equilibration time (~5 min) but a significantly lower equilibrium amount extracted. The combination of an increase in Henry constant and diffusion coefficient to improve kinetics at higher temperature, with a decrease in fiber capacity determined by the distribution constant, contribute to a substantial decrease in extraction time. Therefore, it is important to ensure constant agitation conditions in experiments and acceptable extraction times in order to obtain good precision.

In the third mode, indirect SPME extraction through a membrane (**Figure 4C**), the fiber is separated from the sample with a selective membrane. The main purpose of the membrane barrier is to protect the fiber against damage. Membrane protection is advantageous for determination of analytes having volatilities too low for the headspace approach. In addition, a membrane made from appropriate material can add a certain degree of selectivity to the extraction process. The kinetics of membrane extraction is substantially slower than for direct extraction because the analytes must diffuse through the membrane before they can reach the coating. The use of thin membranes and increased extraction temperatures will result in faster extraction times. Thicker membranes can be used to slow down the mass transfer through the membrane resulting in the time-weighted average (TWA) measurement for aqueous and gaseous samples.

### Extraction Modes with In-Tube SPME

**Figure 5** illustrates the two fundamental approaches to in-tube SPME: (1) active or dynamic, when the analytes are passed through the tube; and (2) passive or static, when the analytes are transferred into the sorbent using diffusion. In both of these approaches, the coating may be supported on a fused silica rod, or coated on the inside of a tube or capillary. The theoretical aspects of the extraction processes that use these geometric arrangements will be discussed below.

**Figure 5** Comparison of (A) passive versus (B) dynamic modes of in-tube extraction.

**Dynamic in-tube SPME** In this system, we assume the use of a piece of fused silica capillary, internally coated with a thin film of extracting phase (a piece of open tubular capillary gas chromatography (GC) column), or that the capillary is packed with extracting phase dispersed on an inert supporting material (a piece of micro-LC capillary column).

The front of analyte migrates through the capillary with a speed proportional to the linear velocity of the sample and inversely related to the partition ratio. For short capillaries with small dispersion, the extraction time can be assumed to be similar to the time required for the center of the band to reach the end of the capillary. The extraction time is proportional to the length of the capillary and inversely proportional to the linear flow rate of the fluid. Extraction time also increases with an increase in the coating/sample distribution constant and with the thickness of the extracting phase but decreases with an increase in the void volume of the capillary. An increase in the coating/sample distribution constant produces an increase in absolute amount extracted. It has been observed in many cases that increases in extraction amounts can be achieved by preconditioning the capillary with methanol or another appropriate solvent prior to extraction.

It should be emphasized that the above discussion is valid only for direct extraction when the sample matrix passes through the capillary. This approach is limited to particulate-free gas and clean water samples. The headspace SPME approach can broaden the application of in-tube SPME. In that case, careful consideration of the mass transfer between sample and headspace should be given in order to describe the process properly. Also, if the flow is very rapid

producing turbulent behavior and the coating/sample distribution constant is not high, then perfect agitation conditions are met and eqn [3] can be used to estimate equilibration times. In this case equilibration time,  $t_e$ , is assumed to be achieved when 95% of the equilibrium amount of analyte is extracted from the sample:

$$t_e = t_{95\%} = \frac{b_t^2}{2D_f} \quad [3]$$

In this equation,  $b_t$  refers to the thickness of the sorbent material, and  $D_f$  refers to analyte diffusion coefficient in the sorbent.

Removal of analytes from a tube is an elution problem analogous to frontal chromatography and has been discussed in detail. In general, if the desorption temperature of a gas chromatogram is high and thin coatings are used, then all the analytes are in the gas phase as soon as the coating is placed in the injector. The desorption time then corresponds to the elution of two void volumes of the capillary. For liquid desorption, the desorption volume can be even smaller since the analytes can be focused at the front of the desorption solvent.

**Static in-tube SPME time-weighted average sampling** An integrated sampling is possible with a simple SPME system. This is particularly important in field measurements when analyte concentrations change with time and location.

When the extracting phase is not exposed directly to the sample but is contained in a protective tubing (needle) without any flow of the sample through it (Figure 5), the extraction occurs through the static gas phase present in the needle. The integrated system can consist of extraction phase coating the interior of the tubing, or it can be an externally coated fiber withdrawn into the needle. These geometric arrangements represent a very powerful method able to generate a response proportional to the integral of the analyte concentration over time and space (when the needle is moved through the space). In these cases, the only mechanism of analyte transport to the extracting phase is diffusion through the gaseous phase contained in the tubing. During this process, a linear concentration profile (shown in Figure 6) is established in the tubing between the small needle opening, characterized by surface area (A) and the distance (Z) between the needle opening, and the position of the extracting phase. The amount of analyte extracted ( $dn$ ), during time interval ( $dt$ ), can be calculated by considering Fick's first law of diffusion:

$$dn = AD_g \frac{dc}{dz} dt = AD_g \frac{\Delta C(t)}{Z} dt \quad [4]$$

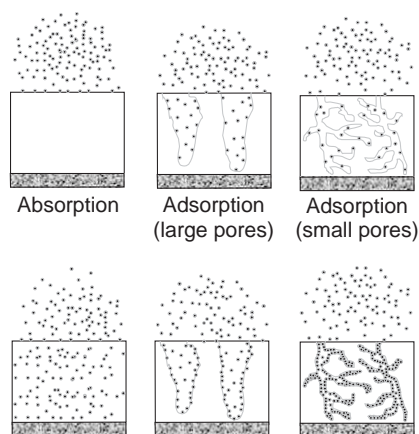

**Figure 6** Use of SPME for in-tube time-weighted average sampling where  $C$  = concentration,  $C_s$  = concentration of analyte in the sample,  $Z$  = distance between needle opening and position of extraction phase, and  $L$  = length of SPME needle: (A) schematic, (B) adaptation of commercial SPME manual extraction holder.

where  $\Delta C(t)/Z$  is a value of the gradient established in the needle between needle opening and the position of the extracting phase,  $Z$ ;  $\Delta C(t) = C(t) - C_z$ , where  $C(t)$  is a time dependent concentration of analyte in the sample in the vicinity of the needle opening, and  $C_z$  is the concentration of the analyte in the gas phase in the vicinity of the coating.  $C_z$  is close to zero for a high coating/gas distribution constant capacity, then:  $\Delta C(t) = C(t)$ . The concentration of analyte at the coating position in the needle,  $C_z$ , will increase with integration time but it will be kept low compared to the sample concentration because of the presence of the sorbing coating. Therefore, the accumulated amount over time can be calculated as:

$$n = D_g \frac{A}{Z} \int C(t) dx \quad [5]$$

As expected, the extracted amount of analyte is proportional to the integral of the sample concentration over time, the diffusion coefficient of analytes in gaseous phase ( $D_g$ ), in the area of the needle opening ( $A$ ), and inversely proportional to the distance of the coating position in respect of the needle opening ( $Z$ ). It should be emphasized that eqn [5] is valid only in a situation where the amount of analyte extracted onto the sorbent is a small fraction (below RSD of the measurement, typically 5%) of the equilibrium amount with respect to the lowest concentration in the sample. To extend integration times, the coating can be placed further into the needle (larger  $Z$ ), the opening of the needle can be reduced by placing an additional orifice (smaller  $A$ ), or a higher capacity sorbent can be used. The first two solutions will result in low measurement sensitivity. An increase of sorbent capacity presents a more attractive opportunity. It can be achieved by either increasing the

**Figure 7** Schematic representation of absorptive versus adsorptive extraction, and adsorption in small versus large pores.

volume of the coating or its affinity toward the analyte. An increase of the coating volume will require an increase of the device size. The optimum approach to increased integration time is to use sorbents characterized by large coating/gas distribution constants.

The exploitation of restricted access to the absorbing medium allows the implementation of SPME for TWA sampling. Where diffusion to the sorbent surface is limited, the sorbent can act as a sort of 'zero sink' such that extraction is very far from equilibrium under normal sampling conditions. In practice then, any analytes reaching the sorbent surface are absorbed, essentially exhaustively. However, the rate of diffusion is still dependent on the sample concentration so the total amount absorbed by the coating is proportional to the average analyte concentration over time, resulting in TWA sampling. This has been implemented to date with the conventional fiber assembly, by retracting the fiber a known distance inside the needle (Figure 6). The small size of the needle orifice limits diffusion to the sorbent surface and the ultimate diffusion rate is also a function of the distance between the fiber tip and the end of the needle. Depending on the volatility and concentration of the analyte of interest, the fiber may be positioned either closer to or further away the end of the needle to achieve the desired degree of nonequilibrium extraction and sensitivity. To date, the retractable needle implementation has gained the most attention, due to its ease of use and adjustability for the analyte and sample at hand.

**Fiber coatings** Substantial differences in performance between the liquid and solid coatings have been observed (Figure 7). In the case of liquid coatings, the analytes partition onto the extraction phase where the molecules are solvated by the coating molecules.

The high diffusion coefficient in the liquid coating allows the molecules to penetrate the whole volume of the coating within a reasonable extraction time, if the coating is thin. In the case of solid sorbents, the coating has a well-defined crystalline structure, which, if dense, substantially reduces the diffusion coefficients within the structure. Therefore, the extraction occurs only within the experimental time on the surface of the coating. There is only limited surface area on the coating available for adsorption. If this area is substantially occupied, the displacement effects occur and the equilibrium amount extracted will vary with concentrations of both the target and other analytes.

One way to overcome the fundamental limitation of the porous coatings is to use an extraction time much less than the equilibrium time so that the total amount of analytes accumulated onto the fiber is substantially below the saturation value. When performing such experiments, is it critical to precisely control extraction times and convection conditions to ensure that they are constant or can be compensated for. One way of eliminating the need for compensation of convection is to normalize agitation conditions.

The short time exposure SPME measurement described has an advantage associated with the fact that the rate of extraction is defined by diffusivity of analytes through the boundary layer of the sample matrix, and their corresponding diffusion coefficients, rather than distribution constants.

The amount of analytes accumulated on the fiber as a function of time for fiber geometry can be estimated as:

$$n = \frac{2\pi D_s L C_s t}{\ln((b + \delta)/b)} \quad [6]$$

where  $n$  is the mass of extracted analyte over sampling time ( $t$ ) in ng;  $D_s$  is the analyte molecular diffusion coefficient in sample matrix ( $\text{cm}^2 \text{s}^{-1}$ );  $b$  is the outside radius of the fiber coating (cm);  $L$  is the length of the coated rod (cm);  $\delta$  is the thickness of the boundary layer surrounding the fiber coating (cm); and  $C_s$  is analyte concentration in sample matrix ( $\text{ng ml}^{-1}$ ).

## Theoretical Aspects of Method Optimization

SPME is a multiphase equilibration process. Frequently, the extraction system is complex, as in a sample consisting of an aqueous phase with suspended solid particles having various adsorption interactions with analytes, plus a gaseous headspace. In some cases, specific factors have to be considered,

such as analyte losses by biodegradation or adsorption on the walls of the sampling vessel. In the discussion below, three phases will be considered: the fiber coating, the gas phase or headspace, and a homogeneous matrix such as pure water or air. During extraction, analytes migrate between all three phases until equilibrium is reached.

The mass of an analyte extracted by the liquid polymeric coating is related to the overall equilibrium of the analyte in the three-phase system. Since the total mass of an analyte should remain constant during the extraction, we have:

$$C_0 V_s = C_f^\infty V_f + C_h^\infty V_h + C_s^\infty V_s \quad [7]$$

where  $C_0$  is the initial concentration of the analyte in the matrix;  $C_f^\infty$ ,  $C_h^\infty$ , and  $C_s^\infty$  are the equilibrium concentrations of the analyte in the coating, the headspace, and the matrix, respectively;  $V_f$ ,  $V_h$ , and  $V_s$  are the volumes of the coating, the headspace, and the matrix, respectively. If we define the coating/gas distribution constant as  $K_{fh} = C_f^\infty / C_h^\infty$  and the gas/sample matrix distribution constant as  $K_{hs} = C_h^\infty / C_s^\infty$ , the mass of the analyte absorbed by the coating,  $n = C_f^\infty V_f$ , can be expressed as:

$$n = \frac{K_{fh} K_{hs} V_f C_0 V_s}{K_{fh} K_{hs} V_f + K_{hs} V_h + V_s} \quad [8]$$

Also:

$$K_{fs} = K_{fh} K_{hs} = K_{fg} K_{gs} \quad [9]$$

since the fiber/headspace distribution constant,  $K_{fh}$ , can be approximated by the fiber/gas distribution constant,  $K_{fg}$ , and the headspace/sample distribution constant,  $K_{hs}$ , by the gas/sample distribution constant,  $K_{gs}$ , if the effect of moisture in the gaseous headspace can be neglected. Thus, eqn [2] can be rewritten as:

$$n = \frac{K_{fs} V_f C_0 V_s}{K_{fs} V_f + K_{hs} V_h + V_s} \quad [10]$$

The equation states, as expected from the equilibrium conditions, that the amount of analyte extracted is independent of the location of the fiber in the system. It may be placed in the headspace or directly in the sample as long as the volumes of the fiber coating, headspace, and sample are kept constant. There are three terms in the denominator of eqn [9] that give measures of the analyte capacity of each of the three phases: fiber ( $K_{fs} V_f$ ), headspace ( $K_{hs} V_h$ ), and the sample itself ( $V_s$ ). Therefore, it is always important to optimize volumes of all the phases present in the system. If we assume that the vial containing the sample is completely filled (no headspace), the term  $K_{hs} V_h$  in the denominator, which is related to the capacity ( $C_h^\infty V_h$ ) of the headspace, can be eliminated, resulting in eqn [1]. Equation [1] describes the

mass absorbed by the polymeric coating after equilibrium has been reached in the system.

Strictly speaking, the above discussion is limited to partitioning equilibrium involving liquid polymeric phases such as polydimethylsiloxane. The method of analysis for solid sorbent coatings is analogous for low analyte concentration, since the total surface area available for adsorption is proportional to the coating volume if we assume constant porosity of the sorbent. For high analyte concentrations, the saturation of the surface can occur resulting in nonlinear isotherms. Similarly, high concentration of competitive interference compound can displace the target analyte from the surface of the sorbent. The simplest way to consider these high concentration effects is to replace the volume of the fiber coating,  $V_f$ , in the above equations as a measure of the total fiber surface area by a fraction of the original coating volume corresponding to a free surface area available for adsorption.

### Prediction of Distribution Constants

In many cases, the distribution constants present in the above equations determine the sensitivity of SPME extraction that can be estimated from physicochemical data and chromatographic parameters. This approach eliminates the need for calibration. For example, distribution constants between a fiber coating and gaseous matrix (e.g., air) can be estimated using isothermal GC retention times on a column with a stationary phase identical to the fiber coating material. This is possible because the partitioning process in GC is analogous to the partitioning process in SPME, and there is a well-defined relationship between the distribution constant and the retention time. The nature of the gaseous phase does not affect the distribution constant, unless the components of the gas, such as moisture, swell the polymer and change its properties.

A useful method for determining coating-to-gas distribution constants employs the linear temperature programmed retention index (LTPRI) system, which indexes compounds' retention times relative to the retention times of *n*-alkanes. This system is applicable to retention times for temperature-programmed gas-liquid chromatography. The logarithm of the coating-to-air distribution constants of *n*-alkanes can be expressed as a linear function of their LTPRI values. The LTPRI values for many compounds are available in the literature; hence, this method allows estimation of  $K_{fg}$  values without experimentation. If the LTPRI value for a compound is not available from published sources, it can be determined from gas chromatographic analysis.

Estimation of the coating/water distribution constant can be performed using eqn [9]. The appropriate coating/gas distribution constant can be found by applying techniques discussed above and the gas/water distribution constant (Henry's constant) can be obtained from physicochemical tables or can be estimated by the structural unit contribution method.

Some correlations can be used to anticipate trends in SPME coating/water distribution constants for analytes. For example, a number of investigators have reported the correlation between octanol/water distribution constant  $K_{ow}$  and  $K_{fw}$ . This is expected since  $K_{ow}$  is a very general measure of the affinity of a compound to the organic phase. It should be remembered, however, that the trends are valid only for compounds within homologous series, such as aliphatic hydrocarbons, aromatic hydrocarbons, or phenols; they should not be used to make comparisons between different classes of compounds, because of different analyte activity coefficients in the polymer.

### Effect of Extraction Parameters

Thermodynamics theory predicts the effects of modifying certain extraction conditions on partitioning and indicates parameters to control for reproducibility. The theory can be used to optimize the extraction conditions with a minimum number of experiments and to correct for variations in extraction conditions, without the need to repeat calibration tests under the new conditions.

Extraction conditions that affect  $K_{fs}$  include temperature, pH, salting, and organic solvent content in water. Extraction temperature increase causes an increase in the extraction rate, but simultaneously a decrease in the distribution constant. In general, if the extraction rate is of major concern, the highest temperature which still provides satisfactory sensitivity should be used. Adjustment of the pH of the sample can improve the sensitivity of the method for basic and acidic analytes. This is related to the fact that unless special coatings are used, SPME can only extract neutral (nonionic) species from water. By properly adjusting the pH, weak acids and bases can be converted to their neutral forms, in which they can be extracted by the SPME fiber. To make sure that at least 99% of the acidic compound is in the neutral form, the pH should be at least two units lower than the  $pK_a$  of the analyte. For the basic analytes, the pH must be larger than  $pK_b$  by two units.

Addition of salt to aqueous samples generally increases the fiber/matrix distribution constants of neutral organic molecules. However, when the analytes are in the dissociated form, a decrease in the amount extracted is observed. This is related to the

fact that the activity coefficients of ionic species in water decrease with the increase in the ionic strength of the solution. It is important, therefore, to first convert the analytes to neutral forms.

### Introduction

There are three primary elements in fertilizers that require analytical determinations: nitrogen (N); available phosphate (AP) for plant uptake expressed as  $P_2O_5$ ; and water-soluble potassium expressed as  $K_2O$ . Procedures are examined to determine values based on the best methods available for the primary elements, secondary elements, micronutrients in fertilizers, and other trace elements. Uniform methods can eliminate problems associated with fertilizer analyses, resulting in agreement between laboratories on a given sample. By following the exact procedures as outlined in an acceptable method, one can expect a reliable and reproducible chemical analysis.

### Types of Fertilizer Materials

#### Dry Fertilizers

There are six main concentrated dry fertilizers produced and used in the majority of all mixed fertilizers. Diammonium phosphate (DAP), mono-ammonium phosphate (MAP), granular triple super-phosphate (GTSP), urea, ammonium nitrate, and ammonium sulfate are currently being manufactured with the following 'grades': 18-46-0, 11-52-0, 0-46-0, 46-0-0, 34-0-0, and 21-0-0, respectively. Water-soluble potassium (0-0-60) and potassium nitrate (13-0-44) are added to concentrated fertilizers to produce mixtures of 10-10-10, 8-8-8, 21-7-14, and many other grades. The formulation of a fertilizer with a 15-15-15 grade represents 15 mass% nitrogen (N), 15 mass% available  $P_2O_5$  (AP), and 15 mass%  $K_2O$ . One example of how a mixed fertilizer can be prepared is shown in **Table 1**.

When mixing dry fertilizers, the size of the fertilizer particles in each material will have a major influence on the chemical analysis owing to the

**Table 1** Example of a dry fertilizer (15-15-15)

Concentrated material	Grade	Weight (kg)	Resulting grade contribution		
			N	P <sub>2</sub> O <sub>5</sub>	K <sub>2</sub> O
Urea	46-0-0	456.5	10.5	0	0
DAP	18-46-0	500.0	4.5	11.5	0
GTSP	0-46-0	152.2	0	3.5	0
Potash	0-0-60	500.0	0	0	15.0
Filler	0-0-0	391.3	0	0	0
Total		2000.0	15.0	15.0	15.0

connection between size and uniform sampling. Chemical fertilizer manufacturers will furnish the size guide number (SGN) and the uniformity index (UI) of each material used in the fertilizer mixture. Mixing dry fertilizers with the same SGN and UI values will result in a well-blended product. When fertilizer products with nonuniform particles are mixed, the blended particles will segregate causing erratic analytical results. Sampling of a dry blend fertilizer is commonly done from a conveyor belt, a conical pile, or a prepackaged container. When obtaining a sample, it is imperative to take a representative sample from the population being analyzed. In the case of a confined population such as a 22 kg bag, the sample can be riffle cut from the total population using a riffing procedure, such as that described by the Association of Official Analytical Chemists (AOAC) or the Association of Fertilizer and Phosphate Chemists (AFPC) Methods Manual. For a large sample such as a silo or conical pile, multiple samples from the sample are taken at varying depths and locations around the perimeter of the pile or silo. A single grab sample is a poor representation of the pile due to particle segregation from sloughing due to gravity. The multiple samples are then composited and riffle cut to obtain a sample for analysis. For conveyor belt sampling, multiple cross-section samples must be taken from the belt and riffle cut after composting to obtain a representative sample. To analyze a dry blend fertilizer a riffle cut fraction of ~227 g is ground using a sample mill that will not subject the sample to undue heat or humidity during and after grinding. Samples of dry blend fertilizer containing DAP will deaminate and lose moisture under heat from grinding, resulting in low nitrogen determinations and high phosphate results. High humidity interferes with a uniform grind, resulting in sample deposited on the mill and caking of the ground sample. After grinding, the sample must be homogenized by rolling the powder on a cloth and sealed in a moisture-resistant container. For a sample to be homogeneous it should pass through a 35-mesh screen after grinding and all the sample ground must be retained for analysis.

Calculations of SGN and UI were originally developed by the Canadian Fertilizer Institute as means for describing the average particle size as well as the distribution of particle sizes in granular products and bulk-blended ingredients. SGN provides for the calculation of average size in millimeters multiplied by 100. UI is the ratio of the 'fine' particles retained at the cumulative 95th percentile to 'coarse' particles retained at the cumulative 10th percentile with the result then multiplied by 100. These two indices are particularly significant when considering bulk blended ingredients since ingredients not within acceptable SGN and UI ranges may segregate in storage potentially resulting in nonuniform application. The accepted uncertainty of  $\pm 10\%$  is generally used when considering granular formulations. The overall average and  $\pm 10\%$  uncertainty are then calculated after which each of the blend ingredients are compared to these values. Ingredients whose SGN and UI values are within the 10% uncertainty are acceptable.

### Liquid Fertilizers

Liquid fertilizers commonly used are UAN (urea and ammonium nitrate mixture) containing 28, 30, and 32 mass% N; anhydrous ammonia, which contains 82 mass% N; superphosphoric acid, which is a concentrated form of phosphoric acid with a grade of 0-70-0; and ammonia reacted with superphosphoric acid to produce a liquid fertilizer of 10-34-0 or 11-37-0 grade. Different liquid grades of fertilizer can be produced using a variety of chemicals for grades similar to the dry fertilizer grades.

## Analytical Methods for Nitrogen

### Formaldehyde Titration – Method 1 (Used for Ammonium Nitrate or Sulfate Nitrogen Only)

Method 1 determines the percentage of ammonium nitrate by reacting formaldehyde with ammonium nitrate, which produces nitric acid. The nitric acid is titrated with a standardized sodium hydroxide solution to a phenolphthalein endpoint or a pH endpoint. The determined percentage ammonium nitrate can be converted to %N by multiplying the percentage ammonium nitrate by 0.349978. The percentage ammonium sulfate can be determined by the reaction of formaldehyde, which produces sulfuric acid. The sulfuric acid can be titrated with sodium hydroxide to determine the amount of ammonium sulfate present. The %N from ammonium sulfate is determined by multiplying the percentage ammonium sulfate by 0.212. Ammonium nitrate in UAN can be determined by this method since the urea will not react. *Note:* Method 1 is of less importance now

and used less because formaldehyde can be a safety hazard if not used properly.

#### **Urease Digestion/Titration – Method 2 (Used for Urea Nitrogen Only)**

Method 2 determines the urea nitrogen by the action of the enzyme urease or Jack Bean on urea, producing ammonia and carbon dioxide. The ammonia is titrated with sulfuric acid to a neutral endpoint using methyl purple as the indicator. A pH meter can be used for a better endpoint determination because of the obscure visual endpoint when using methyl purple. To determine the correct endpoint in the titration, a known sample of urea should be titrated several times to determine the pH endpoint ( $\sim 4.2$ ). Both urea alone and urea in UAN solutions can be determined by this method. The conversion of urea into %N can be accomplished by multiplying the percentage urea by 0.4665. In the case of UAN, the total nitrogen can be found by adding the %N found in the formaldehyde and urease titration methods plus any free ammonia nitrogen present. *Note:* Jack bean meal can be substituted for urease at a much lower cost since it contains sufficient amounts of urease to accomplish the conversion.

#### **Nitrogen Combustion – Method 3 (Used for all Forms of Nitrogen)**

The nitrogen combustion process can analyze both liquid and dry fertilizer samples. In the nitrogen combustion process, all forms of nitrogen are converted to nitrogen gas by incineration. Its effective filament resistance measures the nitrogen gas concentration. Known standards are used to calibrate the instrument before use. There are several manufacturers offering instrumentation for this purpose. This method offers a rapid way to determine the total nitrogen for all forms of nitrogen fertilizers and generating infinitesimally small amounts of chemical waste as compared to the classic Kjeldahl nitrogen method. High cost of maintenance of equipment is a drawback in this method.

#### **Comprehensive Kjeldahl – Method 4 (Used for all Forms of Nitrogen)**

The comprehensive method determines the nitrogen content for all forms of nitrogen compounds (nitrite, nitrate, urea, organic nitrogen, and ammonia), which upon distillation can be collected in a known amount of sulfuric acid and titrated with sodium hydroxide. A great deal of time is consumed in performing this classical nitrogen method. *Note:* Boric acid may be used for collection of ammonia in the distillation step rather than sulfuric acid.

#### **Spectrophotometric Salicylate–Nitroprusside – Method 5 (Used for Ammonia Nitrogen)**

The salicylate–nitroprusside method determines the ammonia nitrogen ( $\text{NH}_3\text{-N}$ ) by reacting ammonia with a salicylate–nitroprusside solution to produce color intensity proportional to the concentration. Automation can be used to analyze multiple samples rapidly for ammonium products and urease conversion digestions. Often, Methods 5 and 9 in combination are analyzed spectrophotometrically for ammonia nitrogen and phosphate using an autoanalyzer.

#### **Ammonia (Nitrogen by Difference) – Method 6 (Used for Anhydrous Ammonia Only)**

Method 6 determines the moisture content of anhydrous ammonia by evaporation and the nitrogen content is determined by subtracting the water content from 100% and multiplying by 0.8224:  $\%N = (100.0\% - \% \text{moisture}) \times 0.8224$ . *Note:* \* % Moisture for anhydrous ammonia can be determined by the AFPC, The Fertilizer Institute (TFI), and AOAC procedures.

#### **Kjeldahl Digestion – Method 7 (Used for Ammonia Nitrogen)**

The Kjeldahl digestion method is used to determine only the ammonia nitrogen content. Sodium hydroxide or magnesium oxide is used to raise the pH to above 12 to liberate the ammonia upon distillation, which is collected in a known amount of sulfuric acid. The excess sulfuric acid is titrated with sodium hydroxide and the percentage ammonia nitrogen is determined. Only ammonia-based fertilizer material should be analyzed using this method.

#### **Refractive Index and Specific Gravity – Method 8 (Used for UAN Solutions)**

Using known concentrations of UAN solutions with various concentrations of water, ammonium nitrate, and urea, a triangular graph can be plotted using refractive index and specific gravity. Each manufacturer develops a curve related specifically to products produced at each location. Owing to slight variations in the manufacturing processes, the triangular graph from one producer may not work for other producers or independent laboratories.

*Note:* Other determinations could be used for nitrogen compounds in fertilizer, such as ion chromatography, spectrophotometric (dye approach), gas diffusion, potentiometric, and indophenol blue methods. These methods have not been approved as official methods by credible organizations such as AOAC International and AFPC. Potentiometric

measurements are typically not as precise and accurate as approved procedures.

*Note:* When determining any nitrogen ingredients in fertilizer, known and blank standards should be used before the final official analysis is stated. Corrections should be made for the blank on all samples and the known standards should be within 0.1% N. If a known NIST (National Institute of Standards and Technology) standard reference material is available, it should be used to verify the method and to verify other internal check samples.

## Analytical Methods for $P_2O_5$

### Indirect Available $P_2O_5$ – Method 9 (Used on all Forms of Phosphate Fertilizers)

Method 9 determines the available  $P_2O_5$  or available phosphate in all types of fertilizer samples. The total  $P_2O_5$  and the citrate-insoluble  $P_2O_5$  are initially determined, and the citrate-insoluble  $P_2O_5$  is subtracted from the total  $P_2O_5$  to give the percentage available  $P_2O_5$  or %AP. Citrate-insoluble  $P_2O_5$  (CI) is the amount not theoretically soluble in a neutral ammonium citrate solution that simulates agronomic conditions. Spectrophotometric and gravimetric methods are used for the determination in all  $P_2O_5$  methods. The indirect AP method has been used longer than any other procedure and demonstrates the best accuracy and precision. The spectrophotometric method utilizes a yellow molybdovanadate complex and the gravimetric method involves a quimociac precipitate. The spectrophotometric method can be completed faster than the gravimetric method using an autoanalyzer system.

### Direct Available $P_2O_5$ – Method 10 (Used on all Forms of Phosphate Fertilizers)

Direct AP methods involve the determination of citrate-soluble  $P_2O_5$  by 'direct' AP analysis after the water-soluble portion is removed. The failure to remove the water washing step before addition to the neutral ammonium citrate will result in oversaturation of the ammonium citrate, resulting in low results. Generally, direct methods are less precise and results have a higher standard deviation. Problems encountered with direct methods are technique, interference of ammonium citrate in the spectrophotometric method, and not using proper acid digestion methods.

### Inductive Coupled Plasma – Method 11 (Used for all Types of Phosphate Fertilizers)

Inductive coupled plasma optical emission spectrometry (ICP-OES) involves elemental excitation through electromagnetic collisional energy. Concentration

measurements are accomplished by conventional spectroscopic instrumentation. Laboratories have used ICP-OES in the past, and the results have been erratic, with lower precision and accuracy (results that are 1–2% lower) than older established methods. As in any method development improvements have been made using the ICP-OES by members of the AFPC.

Determination of phosphorus by using a simultaneous ICP-OES has been achieved as an assay method for rock and high concentrate phosphate products with accuracy and precision comparable to existing spectrophotometric and gravimetric methods. This has been accomplished by matrix matching the standards with the sample, using an internal standard, and buffering the interference effects of calcium and magnesium by introducing lithium nitrate as a buffer. An additional tool that has reduced the interference effects of easily ionizable elements has been robust plasma conditions. These are characterized as low center tube flow of  $0.61 \text{ min}^{-1}$  and a high radiofrequency of 1400 kW. Choice of nebulizer, analyte concentration, and sample introduction protocol varies with each instrument and requires the chemist and the applications specialist to optimize based on signal-to-noise ratios and relative standard deviations of the replicates. Instrument manufacturers are an invaluable source of information when optimizing a new method. The best candidates for internal standard are scandium and beryllium. Yttrium is found in phosphate rock in varying quantities, introducing variability into the results. Further information on the ICP-OES method as described can be obtained from the members of AFPC.

## Analytical Methods for Water-Soluble Potassium

### Water-Soluble Potassium Determinations – Method 12 (Used for Water-Soluble Potassium Fertilizers)

Water-soluble potassium (expressed as  $K_2O$ ) can be determined by manual or automated flame photometric and tetraphenylboron titration methods for all types of fertilizer samples. Atomic absorption can be used for samples below 5%  $K_2O$  to maintain the highest degree of precision and accuracy. (*Note:* Tetraphenylboron method for potassium is being used less often because of safety issues associated with formaldehyde.) Methods using ICP-OES for high concentration of potassium are currently being developed. *Note:* Potentiometric measurements can be used to determine potassium in fertilizers but are not official approved methods and do not meet the accuracy and precision requirements as current methods.

## Slow Release Fertilizers

### Slow Release Fertilizers – Method 13 (Used for all Types of Fertilizers)

The commercial development of slow release fertilizer materials has been incremental and based on the use of several unique technologies over the last ~50 years. While each technology has found a niche in certain specialty markets they have not found widespread use in broad-based agricultural markets. Each technology was addressed, as it was developed, in terms of the regulation and analysis of the specific material. This prompted Association of American Plant Food Control Officials (AAPFCO) to form a taskforce addressing this problem. They identified a need to develop an effective method to evaluate a broad range of materials instead of a number of product-specific methods. Equipped with this, regulators can begin to monitor these materials efficiently in a regulatory laboratory setting. Key components in the method's evolutionary process were developing an accelerated laboratory procedure and a stable laboratory soil leaching system mimicking real-life biological conditions. Having accomplished this, the correlation of the output data from the two new methods can give analysts a statistically reliable method to analyze, characterize, and regulate slow release fertilizer materials.

The laboratory method can be summarized as follows: A representative unground fertilizer sample is exposed to increasingly aggressive solvent extractions. The procedure is designed to rapidly accelerate the release of materials in a matter of hours instead of the normal days or weeks normally experienced. The first extraction is with distilled water at 25°C, subsequent extractions are carried out with 0.2% citric acid at 60°C for increasing periods of time. Each extraction is designed to extract and isolate nutrients that become available over 74 h of extraction time. Extracts are preserved and then analyzed by traditional AOAC procedures for the nutrient of interest. Along with analysis of total nutrients in the sample, data are used to develop information specific to the cumulative percentage of nutrient released over the entire extraction period.

A final report was published by AAPFCO slow release taskforce in August 2004. (The report can be obtained from AAPFCO.) The report summarizes both lab and soil methods as well as correlates the data. Following this presentation the method will be submitted to AOAC for review and publication.

## Trace Elements in Fertilizers

Trace elements for the fertilizer industry are elements occurring at less than 1000 ppm in samples analyzed.

Several classes of elements are routinely analyzed in fertilizers. Secondary nutrients and micronutrients in fertilizers are two classes of trace elements beneficial to plants. Common micronutrients analyzed in fertilizers are Zn, Mn, B, Fe, Mo, and Cu, and secondary nutrients include Ca, Mg, and S.

Trace elements such as As, Cd, Co, Pb, Hg, Mo, Ni, Se, and Zn found in fertilizers causing possible health problems in the transfer of these trace elements into the food chain are under investigation. A scientific risk-based study was performed independently by the US Environmental Protection Agency (EPA), State of California, and The Fertilizer Institute to determine safe levels of trace elements in fertilizer materials. All three studies provided similar results, concluding that the vast majority of fertilizers produced currently in the USA are considered safe when properly applied. Where issues were found, these were exclusively within a small group of micronutrient products that EPA has chosen to regulate under the Recycled Zinc Micronutrient Rule. AAPFCO has developed a model bill SU1P 25 for determining safe levels of trace elements in fertilizers based on the scientific risk-based studies. Several US States, Canada, and other countries have adopted limits on trace elements in fertilizers with some variation in limits. For information on SU1P 25 contact AAPFCO (<http://www.aapfco.org>). For information on metal limits worldwide go to website <http://afpc.net> for the latest data.

### Inductive Coupled Plasma (ICP-OES) – Method 14 (Trace Metals in all Fertilizers)

Matrix matching is the most commonly used tool for overcoming the complex interactions when analyzing secondary, micronutrients, and trace elements under regulation. The procedural tools described in Method 11 are useful in achieving accurate results when analyzing trace elements. In addition to those procedures, using multiple lines for an element is a necessary precaution to prevent a weak line from iron or other elements with multiple spectral lines from influencing the result of a trace element through spectral interferences. When analyzing near the limits of quantification, use of known addition to the samples will confirm a signal response and recovery for a specific element to increase precision.

For the past several years a metals forum has been established to review four different areas associated with trace metals. The four areas include: (1) digestion and reference materials, (2) detection, instrumentation, and data handling, (3) soil analysis, metal availability, and plant uptake, and (4) regulation, enforcement, risk management, and education.

The event is sponsored by AAPFCO, FLDACS, AFPC, TFI, and IMC. For further and current information contact Bill Hall of IMC Global (e-mail: wlhall@imcglobal.com).

## Methods for Different Types of Fertilizers

The previously discussed analytical methods are grouped according to application to specific fertilizer types for nitrogen, phosphate, and potassium. The preferred methods for analyzing N, P, and K fertilizers are listed in Table 2. The specific claims or guarantees on fertilizer products such as ammonia nitrogen, nitrate nitrogen, and urea nitrogen will require different nitrogen procedures beyond a total nitrogen procedure, which may be the method of choice for most analytical determinations.

### Production Application for Nitrogen and Available Phosphate

In the manufacturing plant the grades of MAP, DAP, and GTSP are controlled by analyzing the nitrogen and total phosphate content every 2 h and the citrate insoluble (CI)  $P_2O_5$  every 8 h. Expected CI in these

products is as follows:

	Expected range
MAP	0.0–0.2%
DAP	0.0–0.2%
GTSP	1.0–3.5%

*Note:* GTSP continues to react for several weeks after being produced, reducing the CI content to 0.5–1.5%, or less.

For over 100 years the empirical method for determining AP has been used to make sure that no manufacturer was misrepresenting the products produced. Many years ago, some unscrupulous manufacturers were adding phosphate rock to normal superphosphate (0-20-0) to obtain the final product. In the manufacture of DAP, MAP, and GTSP today it would be impossible to add another product to these high-grade materials and still achieve the grades 18-46-0, 11-52-0, and 0-46-0. The use of phosphate rock, which contains 30–35%  $P_2O_5$ , would dilute both the nitrogen and phosphate grades.

The empirical method for the present concentrated fertilizers would benefit from a new concept for determining the relationship of plant agronomics with regard to phosphate. Agronomists state that only 5–15% of a year's available phosphate application will be available in the first growing season. The remaining phosphate will react with the soil and form insoluble compounds and will be available in future years. The empirical method for AP today restricts these materials from being sold as AP. This so-called insoluble phosphate behaves similarly to the reaction of soil complexation. Over time the CI breaks down and becomes available to plants. A simple solution for high-grade materials would be to sell it on the basis of total phosphate. DAP and MAP were not produced until 1959 and of the previous work on available phosphate none was used in testing of these products.

**Table 2** Recommended methods for specific types

<i>Nitrogen products – percentage nitrogen</i>	
Ammonium nitrate	Methods 1, 3, 4
Ammonium sulfate	Methods 1, 3, 4
Ammonia	Method 6
UAN	Methods 1, 2, 3, 4, 7, 8
MAP	Methods 3, 4, 5, 7
Urea	Methods 2, 3, 4
Fertilizer mixtures	Methods 3, 4
<i>Phosphate products – percentage available and total <math>P_2O_5</math></i>	
MAP	Methods 9, 11
DAP	Methods 9, 11
GTSP	Methods 9, 11
Mixed fertilizers	Methods 9, 11
Superphosphoric acid	Methods 9, 11

<i>Water-soluble potash products – percentage <math>K_2O</math></i>	
Potash, KCl	Method 12
Mixed fertilizers	Method 12
<i>All fertilizers – slow release properties</i>	
All types of fertilizers	Method 13
<i>All fertilizers – trace elements, ppm</i>	
All types of fertilizers	Method 14

## Quality Assurance

In precisely determining the N- $P_2O_5$ - $K_2O$  concentrations in fertilizer samples, a well-designed quality assurance program is essential. The program should contain the following as a minimum: (1) internal standards; (2) duplicate analysis of samples; (3) standard additions; (4) NIST standards; and (5) participation in one or more check sample programs.

Internal standards are prepared from reagent-grade mixtures of potassium dihydrogen phosphate and ammonium sulfate 'primary standards'. Both primary standards are cross-checked with NIST #194 ammonium phosphate to verify the N and  $P_2O_5$  grade and NIST #193 potassium nitrate to verify the

N and K<sub>2</sub>O grades. Internal and 'working' standards are prepared for both N and P<sub>2</sub>O<sub>5</sub> for simultaneous determination using an autoanalyzer. Internal, NIST, and purchased standards should be randomly placed between samples during a group of analytical determinations. Duplicate samples should check within  $\pm 0.2\%$  P<sub>2</sub>O<sub>5</sub> and  $\pm 0.1\%$  N or should be rechecked before the official analysis is given. This is a guideline that must be followed for a high degree of accuracy and precision to be maintained. A laboratory must maintain a good check sample program. There are several excellent check programs dealing with fertilizer materials, and these are detailed below.

### Association of Fertilizer and Phosphate Chemists Check Sample Program

The Association of Fertilizer and Phosphate Chemists administers two check sample (or proficiency) programs that are utilized by manufacturers, customers, and regulatory agencies throughout the world. The AFPC Rock Check Program, formerly known as the IMC Rock Check Program, distributes a 75-g sample of phosphate rock ground to -35-mesh/+200-mesh for determination of major, minor, and trace elements by participating laboratories. The samples are sent monthly at no cost to the participating laboratory. AFPC members from throughout the United States submit rock check samples for distribution. The results submitted by the participating labs are collectively analyzed and the median and standard deviation calculated for each parameter reported. The standard deviation is calculated using the interquartile range, to mitigate the effect of outliers and new participants on the statistical results. The check sample program for high concentrate fertilizers distributes samples of MAP, DAP, GTSP, and Feed Grade Material on a monthly basis and are analyzed for major, minor, and trace elements. Samples are prepared by AFPC members and are distributed at no cost to participants. Results are submitted by participants, and treated statistically as previously described. Information and results on the check sample programs is available on the AFPC website. Both check programs are updated on the web page for the AFPC (<http://afpc.net>) monthly. The AFPC provides archived check samples of rock and fertilizer products for purchase. Further information about the check sample programs can be obtained from the web site or by contacting the AFPC, P.O. Box 1645, Bartow, Florida 33831, USA.

### Magruder Fertilizer Check Sample Program

The Magruder check sample program consists of mixed fertilizers and a few concentrated fertilizers. Example grades such as 13-13-13, 6-24-24, 0-0-50,

6-6-8, 10-10-10, etc., are used in the program. Each month's sample(s) contain the primary plant nutrients N, P, and K; and, about all samples each year contain secondary, micronutrients, and trace elements under regulation. Samples are analyzed by methods chosen by the individual laboratories. A comprehensive statistical summary is prepared, noting interlaboratory bias, precision, and ranking of coded individual laboratories. Subscribers receive this summary to evaluate their performance.

There are ~140 laboratories that subscribe to the Magruder program. All of the US state control laboratories participate, and the remaining number is about equally divided between US industrial and foreign laboratories, the annual subscription fee is \$204 (US) plus postage for foreign countries. For information contact Magruder Check Sample Program (<http://www.magruderchecksample.org/>).

### Internal Goal

Each laboratory using the check sample programs should set an internal goal. Many production and nonproduction laboratories set a goal of falling within one pooled standard deviation on each analysis. A well-established quality assurance program can aid in increasing analytical accuracy and precision to the desired levels. All three check sample programs are highly recommended.

## Introduction

Separations play a central role in the chemical and biological sciences. They are used to prepare products of the required purity, to eliminate unwanted interfering components in analysis, to identify unknown compounds, and in some cases for the measurement of physical properties.

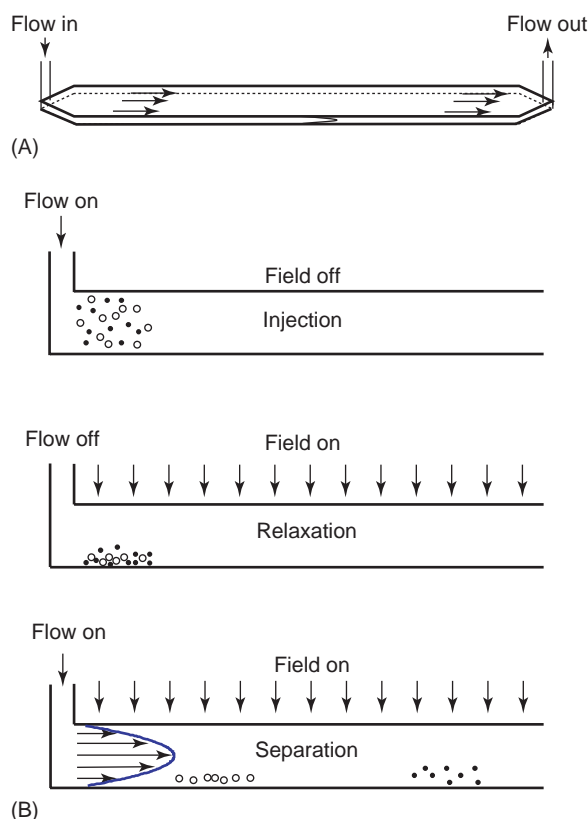

All separation methodologies are based on the selective transport of components in a mixture. This is either due to migration at different velocities in the medium caused by the application of a field or gradient, as in most settling and zone electrophoresis methods, or differences in the distribution of components either across or in the vicinity of a phase boundary, as in liquid extraction or most forms of chromatography.

Field-flow fractionation (FFF) refers to a suite of separation methods that fall into the latter class of separations mentioned above. Basically the solution or suspension is injected into a thin channel, and a field is applied to drive the sample to one wall, where different components take up different distributions across the fluid layer adjacent to the channel wall (**Figure 1**). This partial separation is then magnified by the flow of carrier down the channel, and zones are separated in a manner analogous to chromatography. The applied field may consist of a gravitational, centrifugal, hydrodynamic, or acoustic force, a temperature gradient, or an electrical or magnetic field.

FFF channels are typically 20–100 cm long and 1–4 cm wide but very thin (0.05–0.5 mm). They use the laminar flow of the carrier to effect separation. The construction of a simple FFF channel is depicted in **Figure 2**.

The concept was first developed by the late J Calvin Giddings from 1965 onward, although a similar system was independently reported by Berg and Percell in 1967. The methodology has steadily grown in popularity in recent years, and a range of instrumentation is now commercially available (e.g., Postnova Analytics, Wyatt Technology).

FFF is capable of separating macromolecules and small particles over a very large size range. Molecules from 1000 kDa in molecular weight and particles from ~1 nm up to 50 µm or so can be processed. Although mainly an analytical method for detecting

**Figure 1** (A) Schematic diagram of an FFF channel. (B) Side view of an FFF channel showing the steps involved in separation.

components in a mixture and measuring properties such as size, diffusion coefficients, and mass, it can also be used to collect small fractions for analysis. FFF is ideally suited for connecting to online detectors such as ultraviolet (UV)–visible, fluorescence, and light scattering detectors and inductively coupled plasma (ICP)–atomic emission spectrometers (AESs) and ICP–mass spectrometers (MSs), which can be used to generate distributions of physical and chemical characteristics of heterogeneous mixtures.

## The FFF Concept

FFF is a very flexible set of techniques that can be applied to various sample types with a large range of particle or molecular sizes. This is due to the fact that many different force fields and gradients can be employed and several distinct separation mechanisms are possible. In most cases the field can be varied, often during the course of a particular run (cf. gradient elution chromatography), which extends the size range that can be analyzed. The current size range covered is

**Figure 2** Construction of a simple FFF channel. (A) Plastic sheet spacer; (B) spacer and blocks for forming channel walls; (C) complete FFF channel.

from  $\sim 1$  nm to  $50\text{ }\mu\text{m}$  and for macromolecules from 1000 Da to more than 20 MDa. Brief descriptions of the major modes of operation (separation mechanisms) and fields (FFF subtechniques) that have been used are given in the following sections. Equations are not given in this review, although areas where robust calculations can be made are indicated. Complete listings of FFF equations can be found in the sources given in Further Reading.

### Normal or Brownian Mode FFF

When a sample is injected at one end of the channel the field drives the particles or molecules to the accumulation wall of the channel (Figure 1B). For small particles (say  $<1\text{ }\mu\text{m}$ ), where the Brownian diffusion is comparable with the field-induced flux, diffuse clouds form for each component in the mixture (Figure 3A). The mean thickness of each cloud depends on the balance of the field force and diffusion, which generally depends on the particle size and other particle properties. These clouds are typically  $1\text{--}10\text{ }\mu\text{m}$  thick, compared with the channel thickness of  $50\text{--}500\text{ }\mu\text{m}$ . This relaxation step is usually carried out with the channel flow turned off.

When the flow is resumed, each component cloud is moved down the channel at a different rate, depending on the cloud thickness. This occurs due to the parabolic flow profile in the channel, where the fluid velocity will be zero at the wall and will increase

**Figure 3** FFF separation mechanisms for (A) Brownian (normal) mode and (B) steric/hyperlayer or focusing mode.

with distance from the wall as shown in Figure 3A. Particles with greater interaction with the force field or gradient and/or lower diffusivity (smaller size) will tend to have clouds compressed closer to the accumulation wall and be retained in the channel longer. This was the first FFF mechanism investigated and is most commonly referred to as the normal mode or NIFFF.

At slow flow rates the sample particles have time to diffuse across the cloud many times, ensuring that each will migrate with the mean velocity. At higher flow rates this does not have time to occur and non-equilibrium band broadening results.

One big advantage of normal mode FFF is that certain particle properties such as the buoyant mass, diameter, density, concentration and thermal diffusion coefficients, and electrophoretic mobility can be calculated directly from the elution time or volume of the sample peaks. For example, with flow FFF (see below) the diffusion coefficient and hence equivalent spherical hydrodynamic diameter can be estimated. Other fields enable different properties to be obtained.

### Steric, Hyperlayer, or Focusing Mode FFF

For particles larger than  $\sim 1\text{ }\mu\text{m}$ , Brownian diffusion becomes negligible compared with the field-induced flux. In this case the particle components form layers very close to the wall at positions where the field force is just balanced by a hydrodynamic lift force, which tends to push the particles away from the accumulation wall (Figure 3B). Each sample component is positioned in its individual hyperlayer and is swept down the channel by the corresponding flow lamina, resulting in separation. Particles that have larger sizes and as a consequence experience greater lift forces will be found in hyperlayers that are more

elevated from the accumulation wall and will thus elute earlier than smaller particles. This separation mechanism has variously been called the steric/hyperlayer, lift-hyperlayer, or focusing mode, but for simplicity it is often just referred to as steric FFF.

Due to the complexities of hydrodynamic lift forces, the particle diameter and other physical properties cannot be calculated directly from the measured retention. For this to be done a calibration must be performed using standard particles. The standards must have known characteristics and often need to be of the same material as the samples being analyzed. Separation is based on a number of physical properties such as the diameter, density, and shape.

Sample components can be focused into hyperlayers by forces other than the hydrodynamic lift. Examples include counteracting gravitational forces with a field operating in the opposite direction, as discussed below in the sections on dielectrophoretic FFF and acoustic FFF. The term 'focusing FFF' or FoFFF is sometimes used for this separation mechanism.

### Other FFF Separation Modes

A few other separation mechanisms that can be classified as FFF have been subjected to preliminary investigation. Alternating gravitational and electrical fields have been employed in cyclical FFF (CyFFF). A change in the relative direction of the gravitational field was achieved by periodically flipping the channel 180°. In CyFFF the particles move away from the accumulation wall and then back again: thus different components will move across the parabolic channel flow profile at different speeds and this will affect their migration rate down the channel, resulting in separation.

A chromatographic-FFF hybrid mode has been demonstrated for separating cells. Here the attractive interaction of cells to the accumulation wall, which is normally destructive for FFF operation, is used to separate B and T lymphocytes. Although the cells have very similar sizes and densities, selectivity was achieved because the attachment force was different and this could be balanced by the lift and drag forces of the carrier fluid.

The disadvantage of the small scale of FFF separations can be overcome in two-dimensional continuous devices. Here one FFF subtechnique is employed along the flow axis of the channel and another force vector generates a component of motion at right angles to this (cf. free flow or curtain electrophoresis). The result is that different components move along and across the planar accumulation wall, tracing out different trajectories.

This enables the sample mixture to be continuously fed into the channel, and components can be collected at different outlet ports.

One such device uses a combination of gravitational steric/hyperlayer FFF along the channel axis, and since the channel is mounted at an angle, and not flat on the bench, gravity also causes movement of particles sideways across the channel. A series of outlet ports along the lower edge of the channel continuously removes the separated components.

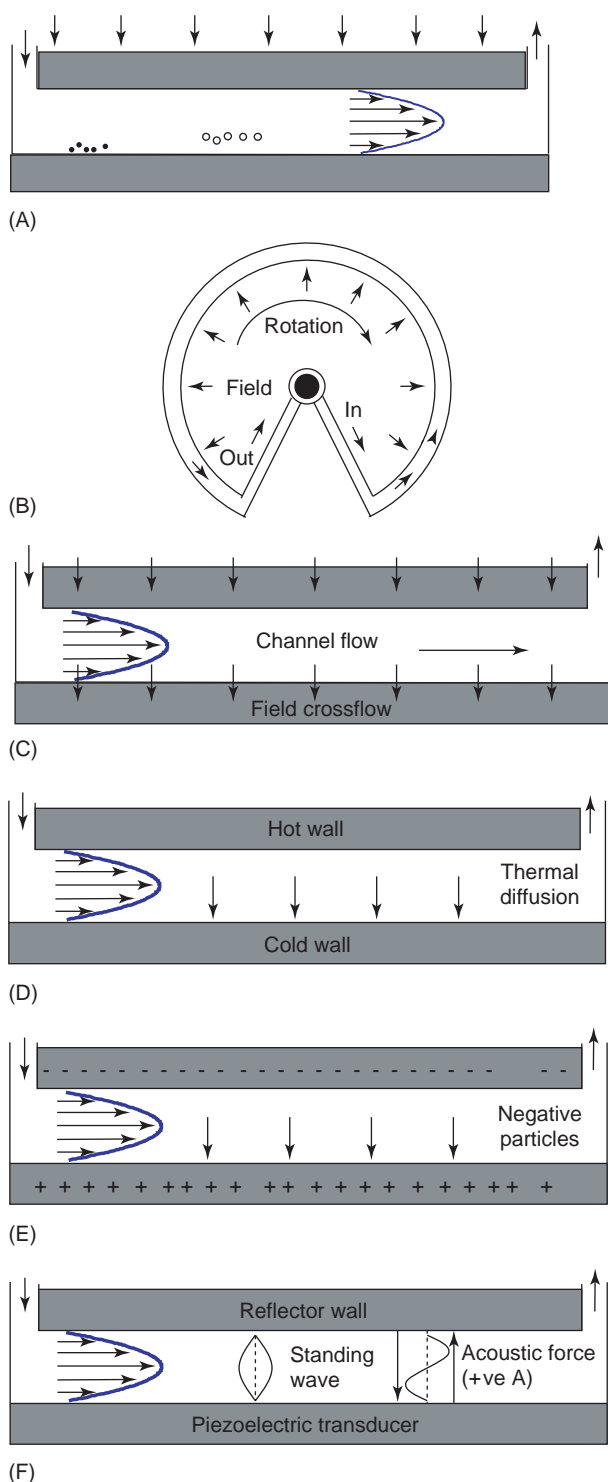

Another recent application uses thermal FFF in the radial direction of a circular channel and fluid shear generated by rotating one wall relative to the other. Polymer mixtures were continuously fed into the channel near the centre, and different molecular weight fractions were removed from the channel at points around the outer circular edge.

### Subtechniques of FFF

Many different fields and gradients have been used to perform FFF experiments, each giving rise to a particular FFF subtechnique. Since each field or gradient will interact with the particles or molecules differently, the resulting separation will depend on different sample characteristics. Consequently, certain subtechniques may be more suited to certain types of samples. In addition, the separation capabilities of normal mode FFF can often be used to measure particle or molecular parameters such as the size, mass, density, and diffusion coefficient. The exact property that can be measured will depend on the field being used. Some common subtechniques of FFF are listed below.

**Gravitational FFF (GrFFF)** GrFFF utilizes the earth's gravitational field, which is only strong enough for particles greater than  $\sim 1\mu\text{m}$  in diameter (**Figure 4A**). Although GrFFF channels are the simplest and cheapest to construct, they are limited to steric/hyperlayer runs of micrometer-sized particles. Examples of GrFFF runs of 5 and  $10\mu\text{m}$  silica particles are given in **Figure 5**. The void peak contains unretained material, and the larger particles elute before the smaller ones.

**Sedimentation FFF** In these instruments the channel is inserted inside a centrifuge basket and the centrifugal acceleration generates the force field (**Figure 4B**). The form of the force exerted on a particle is similar to that produced by gravity, but the magnitude can be much greater, and it can be varied easily by changing the rotational speed. With a centrifuge capable of  $\sim 2500\text{ rpm}$ , particles down to perhaps  $50\text{ nm}$  in diameter can be separated. The resolution is

**Figure 4** Schematic diagrams of the channels used in various FFF subtechniques. (A) Gravitational FFF; (B) Sedimentation FFF; (C) Symmetrical FIFFF; (D) Thermal FFF; (E) electrical FFF; and (F) acoustic FFF.

also the highest for any FFF subtechnique, with the diameter-based selectivity being 3. This means that increasing the diameter by only 10% should increase

**Figure 5** GrFFF fractograms of 5 and 10  $\mu\text{m}$  silica particles.

the elution time by 33%, often resulting in good separation of such peaks.

Both Brownian and steric/hyperlayer FFF are possible, enabling particulate samples between  $\sim 0.05$  and  $50 \mu\text{m}$  to be processed. Normal sedimentation FFF (SdFFF) elution depends directly on the buoyant mass of the particles and hence on a combination of the equivalent spherical diameter (ESD) and density.

**Flow FFF** If the channel is constructed with porous walls (e.g., ceramic or metal frits covered with an appropriate membrane), a second flow stream can be pumped across the channel in order to drive the sample toward the accumulation wall (**Figure 4C**). On reaching the wall, back diffusion in the case of the Brownian mode or hydrodynamic lift forces for larger particles cause the sample components to take up their equilibrium positions. The parabolic fluid flow then causes selective migration along the channel. Molecules as small as 1 kDa and particles 1 nm in diameter can be separated in the Brownian mode. For small particles or macromolecules, elution depends entirely on the diffusion coefficient of the particles: thus the hydrodynamic diameter can be determined, independent of density.

The majority of studies have used a symmetrical flow FFF (SyFIFFF) channel where the cross flow is pumped through a frit at the top of the channel and is removed through the membrane and frit at the accumulation wall as shown in **Figure 4C**. The channel and field flows are usually driven by two independent pumps. In recent times a variant termed asymmetric FIFFF (AsFIFFF) has gained popularity. Here the top wall is an impervious glass or plastic plate and there is a single channel inlet flow. Some of the carrier fluid is taken out through the lower membrane and frit that produces the hydrodynamic 'field', causing the

sample to migrate to the accumulation wall. The remaining flow exits the end of the channel and carries the separated sample components to the detector.

Although the equations governing AsFIFFF are much more complicated than for SyFIFFF, asymmetric channels have the distinct advantage that the operator can see through the top wall and using injected dyes can test the flow pattern in the channel. In addition only one inlet pump is needed and injected samples can be focused into a narrow band during the relaxation period by pumping carrier from both ends of the channel, which reduces band broadening. However, the results from both SyFIFFF and AsFIFFF are comparable.

**Thermal FFF** Macromolecules and particles migrate along a temperature gradient, from hot regions to cold, through a poorly understood phenomenon called thermal diffusion (Figure 4D). If a channel is made of metal blocks, one which is heated and the other cooled, large temperature gradients of  $\sim 10^5$ – $10^6$  °C m<sup>-1</sup> can be generated across the thin dimension of the channel. The cold block becomes the accumulation wall, and components are separated on the basis of the ratio of the concentration diffusion coefficient ( $D$ ) to the thermal diffusion coefficient ( $D_T$ ). Thus if  $D$  is known, thermal FFF (ThFFF) can be used to estimate  $D_T$  values for polymer–solvent combinations. ThFFF has been used extensively for polymer characterization in organic solvents. Since  $D_T$  is independent of molecular weight ( $M$ ) but  $D$  is related to the size and hence  $M$ , ThFFF elution profiles can yield molecular weight distributions, provided a suitable calibration is performed to take into account the variations in molecular conformation that affect the conversion of  $D$  to  $M$ . This calibration procedure is similar to that required for size exclusion chromatography (SEC), and the two techniques are rather complimentary. ThFFF is very effective at high  $M$ , being less prone to artifacts such as stationary phase interactions (adsorption and pore rejection) and shear degradation. Above  $\sim 100$  kDa, ThFFF has a higher resolution, which tends to increase with  $M$ , but separation becomes more difficult below  $\sim 20$  kDa. In recent years ThFFF has been extended to include particles and aqueous phase separations.

**Electrical FFF** A fairly obvious extension is to use an electrical field to separate charged particles and macromolecules on the basis of their electrophoretic mobility and size (Figure 4E). In contrast to the very widely used electrophoresis techniques, the field is used to cause a partial separation of sample components near the accumulation wall, which is magnified

as they are moved along the channel by the fluid flow. Typically quite low voltages (1–2 V) are required since the spacing between the channel wall electrodes of  $\sim 0.1$  mm ensures high voltage gradients are produced. Practical problems such as production of gaseous electrolysis products in the channel and poorly understood double layer effects near the accumulation wall have reduced the separation efficiency. It is likely that some technological advances will appear soon, making this a valuable addition to the FFF family, particularly for protein and cell characterization.

**Magnetic FFF** Magnetic properties of some particles can generate forces in a magnetic field. This principle has been demonstrated with ferromagnetic materials used in tape recording but is of course rather limited. Another approach is to selectively adsorb magnetic nanoparticles to the component of interest. For example, antibody-coated magnetic beads could be used to label important mammalian cell types.

**Dielectric FFF** Dielectrophoretic forces result from the interaction of field-induced polarized particles and a nonuniform AC electrical field. The magnitude of the force depends on the frequency of the applied field and the polarizability of the particles, which in turn is affected by the chemical composition. Gascoyne and coworkers in Texas have performed a separation of human leukocytes in focusing mode FFF, where the gravitational force on the cells toward the accumulation wall was balanced by the upward dielectrophoretic force. Thus the separation illustrated the combined use of two different fields (DI–Gr/FoFFF). This is surely an exciting new development in FFF.

**Acoustic FFF** If an acoustic standing wave is generated across the thin dimension of an FFF channel, particles in the carrier will experience a force, either toward the walls or toward the center of the channel, depending on the sign of the acoustic contrast factor ( $A$ ) (Figure 4F). A ceramic transducer, driven by a megahertz AC voltage, produces the ultrasound wave, and the frequency is adjusted to produce a standing wave between the transducer and reflector plates. The wavelength is chosen to be twice the distance between these plates. For particles with negative  $A$  values (e.g., O/W emulsions, polyethylene) the transducer and reflector become the channel walls and fractionation occurs along each as the force is away from the center line. For particles with positive ( $A$ ) values (e.g., polystyrene, silica, steel) the gap between the transducer and reflector can be at least half-filled with an acoustically transparent gel,

the surface of which becomes the accumulation wall. The acoustic FFF/FoFFF separation principle has been demonstrated using micrometer-sized polystyrene latex, yeast cells, and an O/W emulsion. The acoustic field has also been combined with gravitational forces (Ac-Gr/FoFFF), analogous to DI-Gr/FoFFF, described above. The magnitude of the acoustic force depends on the particle size, density, and compressibility, which again suggests the possibility of separations based on the material properties as well as physical size. New applications for these techniques are being sought in medicine, environmental science, and nanotechnology.

### Field Programming in FFF Runs

With samples that have high polydispersity, it is often advantageous to employ field programming to ensure reasonable run times are achieved. The approach is similar to temperature programming in gas-liquid chromatography and solvent programming in high-performance liquid chromatography. Field programming is sometimes essential for normal mode SdFFF due to the very high-size selectivity ( $S_d = 3$ ), which can result in the larger particles being spread along the elution axis to the extent that they become too dilute to detect. Fortunately, programming is quite simple to achieve in SdFFF as the field is controlled by the centrifuge speed. It should be noted that field programming does not benefit separations of narrowly dispersed samples.

Many different forms of the field program have been employed. They often consist of an initial period of a constant high field followed by a decay of the field to speed up elution of the larger particles. Decay functions have included linear, parabolic, and exponential expressions. One popular decay function, introduced by Williams and Giddings, is referred to as the power program. It has the advantage of producing separations with a constant fractionating power, which means the fractional increase in diameter is proportional to the fractional increase in elution volume.

Field programming is also used in the separation of macromolecules using FIFFF and ThFFF, although since the selectivity is much less than for SdFFF it is not usually essential unless the sample molecular weight (MW) polydispersity is well over an order of magnitude.

### Hyphenated FFF Techniques

The separation capabilities of FFF can be capitalized upon by making physical and chemical measurements

on the fractionated sample. This may be achieved by obtaining discrete subsamples using a fraction collector and performing offline analysis using appropriate instruments. However, a more efficient approach is to connect the channel outlet to one of the various types of online detectors that are available. A few examples of such hyphenated FFF techniques are given below.

**FFF-UV** Traditionally UV absorbance detectors are used to monitor the mass of particles or macromolecules in the eluent. Errors will arise if the size dependence of the attenuation of the light is neglected. For particles that scatter the light beam, this requires correcting the signal using Mie theory, but this is usually not attempted due to the complexity of the computation or lack of information such as the refractive index. For macromolecules where light absorbance occurs, it is assumed that the chromophores are uniformly distributed across the MW distribution. These data are usually plotted in the form of fractograms (analogous to chromatograms), which are plots of detector response versus elution time or volume. The fractograms obtained from UV detectors can be converted to particle size or MW distributions either using the FFF equations or when necessary calibration standards to convert the elution time axis to diameter or MW.

**FFF-multiangle light scattering (MALS)** MALS detectors enable the MW of eluted macromolecules to be measured online. When combined in series with a mass detector such as a UV or refractive index detector, the MW distribution is generated directly without any calibration with standards. Furthermore, MALS also yields the radius of gyration of the molecules and the variation of this size parameter with MW can be used to deduce molecular conformation information.

**FFF-ICP-MS** The ICP-MS is a multielement analysis tool ideally suited for direct coupling with FFF. The ICP torch is capable of vaporizing and ionizing particles in the eluent up to  $\sim 10\ \mu\text{m}$ , and the plasma is then fed into an MS for simultaneous detection of many elements. Quadripole, mass-sector, and time of flight MSs are now available, depending on the sensitivity, mass resolution, and response time required. FFF-ICP-MS yields element-based size distributions. Other element detection systems that have been used include ICP-AESs, electrothermal atomic absorption spectrometers, and very recently laser-induced breakdown spectrometers.

## Applications of FFF

### Particle Separation

The range of particles that have been analyzed using FFF is huge, ranging from minerals to polymer latexes, emulsions, metals, carbon black, carbon nanotubes and onions, pigments, bacteria, viruses, casein micelles, starch granules, and yeast and mammalian cells, to name a few.

Perhaps the biggest issue that must be confronted in particle separation is the normal–steric transition that occurs at  $\sim 1\ \mu\text{m}$ . The problem arises because the elution order of particles in the normal and steric modes is opposite (increasing size with increasing elution time for normal mode, but the opposite trend in the steric mode). Thus for broad populations spanning the transition diameter it is possible for fractions eluted at a specific time (or volume) to contain two populations, submicrometer particles that have eluted in the normal mode and micrometer particles eluted in the steric mode.

It is not possible to specify the exact diameter where the normal–steric transition occurs as a loss of selectivity and resolution will be observed in the approximate range  $0.5\text{--}2\ \mu\text{m}$  and this will be affected by the field strength. The simplest general advice that can be given is that if the sample spans  $1\ \mu\text{m}$ , then it should be split into two fractions ( $<1\ \mu\text{m}$  and  $>1\ \mu\text{m}$ ) before attempting FFF separation. Available methods for achieving this prefractionation include settling, centrifugation, filtration, split-flow thin-channel fractionation, and elutriation.

For the above reason, we will consider applications of FFF for submicrometer and micrometer particles separately.

**Submicrometer particles** Particles below  $\sim 1\ \mu\text{m}$  in diameter can be separated using normal mode FFF using a variety of subtechniques, the most widely used being sedimentation and flow. FIFFF can be used down to  $1\ \text{nm}$  and yields the diffusion coefficient and hence the equivalent spherical hydrodynamic diameter distribution. SdFFF instruments usually operate up to  $\sim 2500\ \text{rpm}$ , which can resolve silica particles down to  $\sim 50\ \text{nm}$ . The quantity directly measured is the effective or buoyant mass, and particle size distributions can be generated if the density of the particles is known.

Shape is not a huge concern in these measurements, although for accurate work it should be considered. Shape will influence the conversion of the diffusion coefficient ( $D$ ) to the hydrodynamic diameter in FIFFF, although the discrepancy in  $D$  between spheres and ellipsoids of the same volume will seldom exceed 50%. For SdFFF the buoyant mass

determined will not be influenced by shape unless the particles are very highly retained so that the cloud thickness is less than the largest particle dimension.

An interesting extension of SdFFF measurements is the determination of the particle density. Since the elution time enables the buoyant mass to be estimated from the FFF equations, then if the size of the particles eluted at a given time is measured independently, for example, using electron microscopy or dynamic light scattering, then the density can be calculated. Alternatively if the elution times of a sample are determined in a series of carriers that have different densities, the particle density can be extracted.

FFF methods are certainly developing into important techniques for colloidal particles. They compare well with other particle sizing techniques for resolution and accuracy, and usually calibration standards are not necessary. The fact that separation is employed helps in obtaining high quality particle size data for polydisperse samples and enables fractions to be examined using other physical and analytical techniques. A drawback is the fact that the separation is truly microscale, with typically  $10\text{--}100\ \mu\text{g}$  being processed in a single run.

**Micrometer particles** As outlined above, micrometer size particles are separated in the steric/hyperlayer mode of FFF, and calibration using suitable standards is required (examples of typical fractograms are given in Figure 5). Shape will be a crucial factor as the lift force is highly shape dependent and can make a difference of two to three times in the elution time of particles with the same volume and mass. For SdFFF and GrFFF, the separation density will also be important, and standards with the same density as the samples must be used or careful adjustment of the field (rpm) applied for the standards, and the sample can be used to compensate for the difference in density. Fortunately, if FIFFF channels are operated with a vertical orientation, so the cross flow is horizontal and the channel flow is vertical, the particle density has no effect on the retention.

Calibration lines are often plotted as  $\log t_r$  versus  $\log d$ , where  $t_r$  is the elution time and  $d$  is the particle diameter, and a straight line is commonly obtained. This enables the  $t_r$  axis of the sample fractogram to be converted to a size axis. Further manipulation of the detector response will be required to generate the particle size distribution as outlined in detail in Further Reading.

There is probably less incentive to resort to FFF analysis for micrometer-size particles than there is for colloids as other adequate methods are available in this range. Examples include single-particle

counters (electrozone, optical blocking, flow cytometers), Fraunhofer diffraction, settling, and elutriation. For FFF the biggest source of concern is the effect of shape on the elution time, which introduces uncertainty in the size determinations. However, separations have high resolution, can cope with broad distributions, and provide small fractions for subsequent analysis. In particular, GrFFF is cheap, can easily be constructed from readily available components already used in liquid chromatography and flow injection analysis, and is simple to operate.

### Macromolecule Characterization

**Thermal FFF** Polymers dissolved in nonaqueous solvents have usually been analyzed using ThFFF. The MW range has varied from  $\sim 5000$  Da up to possibly 100 million. ThFFF is a direct competitor to SEC as a method of MW determination, although they are best seen as complimentary techniques. SEC has better resolution at low MW values, but ThFFF excels at the high MW end. The crossover in terms of resolution probably occurs  $\sim 50$ – $100$  kDa, although this will depend on a number of factors.

ThFFF fractograms can be converted to MW distributions using standards of the same polymer. Universal calibration curves analogous to those used in SEC are possible only for polymers with known thermal diffusion coefficients ( $D_T$ ).

The dependence of retention on  $D_T$  has been used to develop a method for determining this constant, which is difficult to do using other methods. This has resulted in an expansion in the number of polymer types that now have tabulated  $D_T$  values that may contribute to the development of theories for the thermal diffusion process.

It is now known that  $D_T$  does not depend on the MW but is related to the chemical nature of the polymer and solvent. This can be used to advantage to separate different polymers with the same diffusion coefficient and size, which cannot be achieved using SEC. It was found that for random copolymers  $D_T$  is linearly related to the proportion of the amount of the two monomers present, providing a way of measuring the composition of such copolymers. Further, for block copolymers,  $D_T$  apparently depends on the polymer block occupying the outer layer of the copolymer molecules. This could perhaps provide a method of studying the conformation of block copolymers in solution.

Two very important advantages of ThFFF lies in the low shear experienced in the unpacked channel and the lower chance of wall interactions compared with the problems experienced in SEC with pore rejection and stationary phase adsorption. These

effects are of particular significance for ultrahigh MW samples, where shear degradation and low sample recovery are often encountered in SEC.

Another application where ThFFF is very useful is in the characterization of polymers that contain both dissolved molecules and gel particles. Such samples cannot be injected into SEC columns but can be analyzed using ThFFF, where the channel is open and will not be clogged.

ThFFF is most often used for polymers dissolved in organic solvents as samples dissolved in water often have low  $D_T$  values and hence poor retention. However, there are some studies on particle separations and aqueous systems, and this may expand the range of ThFFF applications in the future.

**Flow FFF** Water-soluble macromolecules are usually characterized using FIFFF. The diffusion coefficient and hydrodynamic diameter are determined directly, but these can only be converted to MW using calibration standards of the same type as the sample to ensure the molecular conformation is similar.

FIFFF has been found to be very useful for separation of proteins. In addition to MW and size, molecular conformation and aggregation can be investigated.

Most difficulties encountered with FIFFF are associated with the correct choice and installation of the membrane. Adsorption or repulsion of the sample can cause delayed or early elution, resulting in errors in size and MW, poor resolution, or low sample recovery. No doubt these problems will be reduced as a better understanding of membrane-sample interactions is obtained.

### Introduction

Fire assay describes a group of separation methods in which precious metals (PMs) are separated from other species by dissolution in other molten metals, usually lead, nickel, or tin. Fire assay has been and continues to be fundamental to the determination of PMs. These are defined as gold (Au), silver (Ag), and the platinum group metals (PGMs) platinum (Pt), palladium (Pd), rhodium (Rh), iridium (Ir), ruthenium (Ru), and osmium (Os). In the context of fire assaying other elements are referred to as base elements or metals.

The Further Reading section lists some of the excellent texts available that cover the practical operation of these methods. Bugbee's book, although written 70 years ago, is still relevant to the classical lead, scorification, and cupellation assays. The more recent book by Lenahan and Murray-Smith provides comprehensive cover of practice in the South African mining industry and includes very good discussions on laboratory layout and practice in the calculation of charges for the fire assay. The books by Beamish and Beamish and Van Loon give a very good overview of fire assay in general PM analysis and in

the former there is an excellent section on the calculation of the composition of the assay charge **Figure 1**.

The text by Van Loon and Barefoot contains a chapter on fire assay in the context of instrumental analysis. In this there is comprehensive information on the charges used for a wide range of minerals and ores and several detailed procedures combining fire assay with an instrumental finish are described. Even though modern instrumentation is fairly tolerant of the many interferences found in PM-containing samples, fire assay is still essential at the start of many analytical procedures. Moreover, whether the finish is gravimetric or instrumental, fire assay can offer greater accuracy and precision in sample preparation than many other procedures. This is because it can be used as a separation or preconcentration technique, or both, and it also allows the use of large samples (trials).

### Introduction

Fire assay describes a group of separation methods in which precious metals (PMs) are separated from other species by dissolution in other molten metals, usually lead, nickel, or tin. Fire assay has been and continues to be fundamental to the determination of PMs. These are defined as gold (Au), silver (Ag), and the platinum group metals (PGMs) platinum (Pt), palladium (Pd), rhodium (Rh), iridium (Ir), ruthenium (Ru), and osmium (Os). In the context of fire assaying other elements are referred to as base elements or metals.

The Further Reading section lists some of the excellent texts available that cover the practical operation of these methods. Bugbee's book, although written 70 years ago, is still relevant to the classical lead, scorification, and cupellation assays. The more recent book by Lenahan and Murray-Smith provides comprehensive cover of practice in the South African mining industry and includes very good discussions on laboratory layout and practice in the calculation of charges for the fire assay. The books by Beamish and Beamish and Van Loon give a very good overview of fire assay in general PM analysis and in

the former there is an excellent section on the calculation of the composition of the assay charge **Figure 1**.

The text by Van Loon and Barefoot contains a chapter on fire assay in the context of instrumental analysis. In this there is comprehensive information on the charges used for a wide range of minerals and ores and several detailed procedures combining fire assay with an instrumental finish are described. Even though modern instrumentation is fairly tolerant of the many interferences found in PM-containing samples, fire assay is still essential at the start of many analytical procedures. Moreover, whether the finish is gravimetric or instrumental, fire assay can offer greater accuracy and precision in sample preparation than many other procedures. This is because it can be used as a separation or preconcentration technique, or both, and it also allows the use of large samples (trials).

## Types of Fire Assay

There are three major categories within the overall description of fire assay.

1. Procedures variously termed crucible fusion, pot fusion, or pot running.
2. Scorification.
3. Cupellation.

One or more of these procedures may be used in any individual analytical scheme, depending on the type of sample being assayed and the final elements to be determined and their concentration.

### Pot Fusion

This procedure involves the melting of the sample with a variety of powdered reagents to give a metallic (collector) button (e.g., lead) containing the elements of interest or the metalliferous portion, separated from a slag that contains the unwanted portion of the sample, known as the gangue.

Of the reagents added there are first those that produce the collector. This is usually an oxide with the attendant reducing agent to produce the metallic collector. Second, there are those fluxing reagents (the charge) that help break down the sample and carry away the gangue into the slag portion of the melt. If these components are intimately mixed, as the temperature rises a series of reactions takes place in the molten and semimolten state. First the collector is reduced to tiny globules of metal that are distributed throughout the charge. As the temperature rises further the charge begins to react, the slag begins to form, and the collector begins to function. As the temperature reaches its maximum the reaction is completed and the collector falls to the bottom of the pot with a fluid molten slag on top. Thus, after ensuring a successful fusion the charge can be separated by pouring the molten mixture into an iron mold and allowing it to separate and solidify prior to a physical separation. The separation process is by gravity, the heavier metalliferous portion containing the PMs settling to the bottom of the mould.

The chemistry of the fusion process is complex and in many cases not fully characterized owing to the variety of samples assayed. However, good approximations of the reactions can be made and these help in the estimation of the content of charges as described later. Nevertheless, pot fusion is essentially an empirical process, which accounts for laboratories' different assaying conditions for similar materials.

In the past the assaying conditions would have been determined by a series of trial assays based on

one's knowledge of the sample. This still occurs but many laboratories now have an inductively coupled plasma-atomic emission spectrometer (ICP-AES), whereby a fast and fairly accurate assessment of the composition of the gangue can be made by analyzing solutions prepared from fusion of the material in sodium peroxide.

Once the gangue composition is known, by reference to the molten state chemistry involved one can establish the appropriate amount of reagent required to obtain a successful assay.

Several factors affect the success of a pot fusion and they will now be discussed in turn.

**The sample under test** This is the primary factor in the assay as it is the nature of the sample and the information required that will govern all decisions that will subsequently be made.

Samples will be acidic, basic, or amphoteric, and it is this breakdown that will determine the fluxing reagents added to give a good slag. Along with the elements requiring determination the gangue content will affect the collector chosen. There is also the question of any pretreatment necessary. The components of a sample can be broken down as shown in **Table 1**.

Other factors affecting the assay that are imparted by the sample are its reducing or oxidizing power. As pot fusion is a reducing process, the reducing or oxidizing power of a sample will affect the amount of metallic collector formed in the reaction. This will in turn affect the quantities of reagent added as the final collector button size has to be controlled. For instance, samples containing sulfides, arsenides, antimonides, and carbonaceous matter will be reducing and will reduce litharge (PbO) to lead in the reaction mixture. Samples containing iron(III) oxide and manganese(IV) oxide will oxidize a proportion of the lead (or other collector) or will react with the reductants added, thus decreasing their effectiveness. Generally, siliceous, oxide, and carbonate ores remain neutral with respect to oxidation and reduction.

**Table 1** Sample components

#### *Acidic components*

SiO<sub>2</sub>, B<sub>2</sub>O<sub>3</sub>, WO<sub>3</sub>, As<sub>2</sub>O<sub>5</sub>, Sb<sub>2</sub>O<sub>5</sub>, Bi<sub>2</sub>O<sub>5</sub>, V<sub>2</sub>O<sub>5</sub>

#### *Amphoteric components*

Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub> can take on amphoteric or acidic properties depending on the conditions

Bi<sub>2</sub>O<sub>3</sub>, As<sub>2</sub>O<sub>3</sub>, SnO<sub>2</sub>

ZnO can take on amphoteric or basic properties depending on the conditions

#### *Basic components*

FeO, Fe<sub>2</sub>O<sub>3</sub>, Cr<sub>2</sub>O<sub>3</sub>, CoO, CaO, MgO, MnO, PbO, CuO, Na<sub>2</sub>O, K<sub>2</sub>O

The reducing components of a sample can often be removed by roasting in air prior to the fusion reaction. This will remove sulfur dioxide and carbon dioxide and may partly volatilize arsenic, antimony, and tellurium or otherwise turn them from the reducing chalcogenides to relatively neutral oxides in terms of oxidizing properties.

**Vanning** It was mentioned above that ICP-AES can be used to give an estimate of the composition of the sample so that suitable charges of reagents can be prepared. A time-honored, alternative method of estimating mineral content is by the procedure of vanning. A vanning pan has a spherical surface and could be a watch glass or a purpose-made, white enamel, vanning shovel. About 1 g of sample is placed in the center of the pan and is wetted with water. By manipulation of the pan the water is made to flow through the sample in one direction and effectively separates the minerals by gravity. Clay particles will be suspended easily and can be washed out whilst heavy minerals such as galena will resist any movement with the water. This movement allows the minerals to stratify in a fan-like shape because of their differing specific gravities. One can then apply simple tests to identify the major components of the sample. For instance, the white minerals calcite and quartz differ in their hardness, whereas carbonates and some sulfides will react with acid.

**The collector** The choice of collector is made with a view of not only the PMs of interest but also of the subsequent analytical measurements. The four major collectors in use are lead, nickel sulfide, copper, and tin.

**Lead** This is by far the most common collector in use worldwide. It can be used as red lead,  $Pb_3O_4$ , or more commonly nowadays as litharge,  $PbO$ . Litharge is widely available and can be obtained in a purer state than red lead.

The litharge is intimately mixed with the assay charge. When reduced to lead the fine particles of metal fall through the charge 'like rain' collecting the PMs at the bottom of the melt.

Whilst lead will collect all PMs it is best for determining gold, silver, platinum, and palladium. Although rhodium, ruthenium, iridium, and osmium can be collected, the chemical separation after the fire assay is rather long and tedious.

With lead collection sulfur can prove a problem if not properly dealt with. It can be absorbed into the lead button and form a matte layer, or regulus, into which some PMs will collect, and this will give subsequent problems in the analysis. Lead oxide can be used as a basic flux and if added in excess can

react with sulfur to prevent the formation of a regulus. However, for high sulfur levels alternative steps must be taken to remove sulfur, such as roasting in air prior to the fusion.

**Nickel sulfide** This matte is preferred as a collector when the insoluble (in aqua regia) platinum metals are being sought, i.e., rhodium, ruthenium, iridium, and osmium. It is also a very good collector for platinum and palladium, but it is less effective than lead for the collection of gold and great care must be taken with the fluxing agents to maximize recovery.

Nickel is often associated with the PMs in nature, a good example being the ore body at Sudbury, Ontario, so one must be very careful to obtain a supply of nickel that contains a very low and known content of PMs. The usual chemicals used are nickel powder, nickel carbonate, or nickel oxide with flowers of sulfur, but for the determination of very low PM contents 'carbonyl' nickel (prepared by thermal decomposition of  $Ni(CO)_4$ ) or ceramic grade  $NiO$  are preferred.

When the fusion takes place the nickel species and the sulfur combine to form a matte button of nickel sulfide.

Many of the platinum group minerals exist as sulfides, such as cooperite ( $Pt(AsS)_2$ ) and bragite ( $Pt \cdot Pd \cdot NiS$ ), which undoubtedly enhances their collection.

A practical issue with nickel sulfide buttons is that although appearing metallic to the eye they are very brittle and must be carefully separated from the slag. Tapping gently with an old-fashioned toffee hammer provides excellent separation.

**Tin** This is used as a collector after addition as  $SnO_2$  in an analogous manner to  $PbO$ . It is not widely used but it does effectively collect all PMs. However, there may be problems with the subsequent analysis for all but platinum, palladium, and gold, which may explain its lack of popularity.

**Copper** This is used on its own and also in conjunction with iron and nickel. It can be used for all PMs but it is not as effective in general terms as the other collectors mentioned. However, copper does give good results for gold, silver, platinum, and palladium and has the advantage of being easily melted into a form suitable for an X-ray fluorescence finish with addition of extra copper to standardize the weight of the button. For details of the  $CuFeNi$  collection the reader is referred to the book by Beamish.

**Use of co-collectors** Sometimes it is useful to add small quantities of PM to help in the collection or

subsequent analytical process. In this respect silver can be added in the lead collection of gold and platinum to help with the collection of other PGMs. If this procedure is used one must pay attention to the purity of the co-collector and run concurrent blanks, otherwise results, especially at very low levels, will have a high bias.

**Reducing and oxidizing agents** The term ‘reducing power’ as used in fire assay refers essentially to the removal of oxygen. For a sample or reagent it is that amount of collector that will be formed as a button when an excess is fused with 1 g of sample or reagent. Similarly, the ‘oxidizing power’ is that amount of collector or the equivalent of reducing agent that will be oxidized by 1 g of sample or oxidizing agent. With respect to lead the reactions that occur with some common reducing agents are as follows.

With charcoal as reductant there are two reactions, at low temperature, as in reaction [I],

and at high temperature, as in reaction [II],

Thus, 1 g of charcoal should provide a button of 34.5 g of lead if excess litharge is used.

With wheat flour as reductant the reaction provides 15.3 g of lead from 1 g of flour (reaction [III]):

The reaction with cream of tartar is more complex and provides 5.5 g of lead per gram of reagent (reactions [IV]–[VI]):

In practice, the air above a fusion mixture will oxidize an amount of the carbon produced and thus the actual power of a reducing agent is somewhat less than theoretical; but reasonable estimates can be given as in Table 2.

Besides these reductants the components of a sample can reduce the collecting agent that could lead to a larger button than planned. For lead the most important of these are probably sulfur, iron, and sulfides.

The reducing power of sulfur and sulfides depends on the other constituents of the melt. For instance, the simple reaction is as in reaction [VII]:

**Table 2** Reducing and oxidizing power

<i>Reducing agents</i>	<i>Oxidizing agents</i>	<i>Sample components</i>
Flour 10–12	$\text{KNO}_3$ 4.2	<i>Reducing</i>
Charcoal 18–30		$\text{FeS}_2$ 9–13
Tartar (KH tartrate) 5–6		$\text{FeS}$ 9
		$\text{Fe}$ 4
		$\text{PbS}$ 3.4
		<i>Oxidizing</i>
		$\text{Fe}_2\text{O}_3$ 1.3
		$\text{MnO}_2$ 2.4
		$\text{Fe}_3\text{O}_4$ 0.9

But in the presence of alkaline carbonates the reaction is modified as shown in reaction [VIII]:

Hence, the reducing power of sulfur can be from 12.9 to 19.4 (grams of lead) depending on the conditions of fusion. Potassium nitrate, or nitre, is the most commonly used reagent deliberately added to an assay charge, usually to control the effect of sulfides. In these cases one must consider the other components of the charge or else very undesirable reactions can occur. For instance, if no silica is present the nitre will react with  $\text{FeS}_2$  to produce iron[III] oxide, an undesirable component to have in a fusion mixture (reaction [IX]):

If alkali metal carbonate is absent the sulfur is partially oxidized via reaction [X]:

but if the components are balanced the iron may be reduced and removed completely into the slag along with the sulfur via reaction [XI]:

A practical point to note when using nitre is that it decomposes to produce oxygen. Hence, if used in excess it can produce frothing in the pot, sometimes violently with associated losses, and this must be avoided.

Samples containing species such as  $\text{FeS}_2$  will affect the amount of collector produced. Depending on the conditions lead can be produced by reactions [XII]–[XIV]:

The relevant fact is the reducing power for these reactions. Approximate figures for reducing and oxidizing power are given in **Table 2**.

The point of these calculations concerns the production of a successful fusion and correctly sized button. The usual mass of lead button aimed for is 30–60 g. If the button is too small there is the possibility of incomplete recovery of PMs; if it is too large the problem may be in the subsequent analytical work.

**Fluxing agents and slag formation** The qualities sought of a good assay slag are as follows:

1. It should have a relatively low formation temperature.
2. It should be fairly thick on formation to hold up particles of sample and collector thus allowing total breakdown of the sample and efficient separation and collection of the PMs.
3. It should be thin and fluid when heated above its melting point to allow adequate mixing, good settling of the collector, and an even pour.
4. It should not attack the crucible walls to any degree.
5. It should have a very low capacity for the PMs.
6. Its relative density should be low to give good separation of slag and button.
7. It should physically separate readily from the button after cooling.
8. It should contain all unwanted material from the sample and be clear, indicating complete decomposition.

Various agents may be used to give a good slag. The common fluxing agents are given in **Table 3** and again they can be divided according to acidity.

The fluxing agents and the sample components react to form a series of silicates and borates. Various compounds can be formed with differing acidities but the preferred slag is the balanced bisilicate and metaborate as shown in **Table 4**. The acidity increases going down each series but the typical reactions to consider, for a metal oxide, RO, and a sulfur-containing sample, are as in reactions [XV]

and [XVI]:

Excess lead oxide will form  $\text{PbSiO}_3$  with silica.

**Borax (sodium borate)** It is important to use the dehydrated form for, if water of crystallization is present, there is a danger of the charge being pushed out of the pot. Molten borax is an excellent solvent for nearly all the metal oxides. When it first melts at  $\sim 750^\circ\text{C}$  it is quite viscous but as the temperature increases it becomes a free-flowing liquid that is strongly acidic. In this phase it lowers the melting point of the slag and is particularly effective in dissolving inert materials like bone ash and clay. At  $\sim 500^\circ\text{C}$  it decomposes to  $\text{Na}_2\text{O}$  and  $\text{B}_2\text{O}_3$  with the boron oxide readily forming borates with basic oxides. The different borates are classified above but here one must consider the ratio of basic to acidic oxygens; the best ratio is 1:3 as in the metaborate.

If too large an excess of borax is added to the charge then the fluidity of the melt is diminished with subsequent retention of lead or other collector, and thus PMs, in the slag.

**Alkali metal carbonate** Sodium carbonate is a very powerful basic flux and will readily form silicates. It melts at  $850^\circ\text{C}$  whilst at  $950^\circ\text{C}$  it decomposes to  $\text{Na}_2\text{O}$  and  $\text{CO}_2$ . It can hold carbon and other infusibles in suspension and act as a desulfurizing agent. When initially introduced to the furnace it can form dust, with possible losses. This can be prevented by covering the charge with a thin layer of NaCl. Potassium carbonate behaves similarly, melting at  $890^\circ\text{C}$ . It has the disadvantage of deliquescing and it is more expensive.

**Silica** This is a strongly acidic flux and is usually added as silver sand. If there is high silica content in the sample it may not be necessary to add any, but if the charge is deficient in silica,  $\text{PbO}$ ,  $\text{CuO}$ ,  $\text{FeO}$ , and borax can attack the walls of the crucible. Also, a deficiency can lead to the formation of a matte in

**Table 3** Fluxing agents

Basic	Acidic	Neutral
$\text{Na}_2\text{CO}_3$	$\text{SiO}_2$	$\text{CaF}_2$
$\text{K}_2\text{CO}_3$	$\text{Na}_2\text{B}_4\text{O}_7$	$\text{NaCl}$
$\text{PbO}$		$\text{LiBO}_2$
$\text{Na}_2\text{B}_4\text{O}_7 = \text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ and $\text{LiBO}_2 = \text{Li}_2\text{O} \cdot \text{B}_2\text{O}_3$ .		

**Table 4** Silicates and borates of bivalent base RO

Subsilicate	$4\text{RO} \cdot \text{SiO}_2$	Orthoborate	$3\text{RO} \cdot \text{B}_2\text{O}_3$
Monosilicate	$2\text{RO} \cdot \text{SiO}_2$	Pyroborate	$2\text{RO} \cdot \text{B}_2\text{O}_3$
Sesquisilicate	$4\text{RO} \cdot 3\text{SiO}_2$	Sesquiborate	$3\text{RO} \cdot 2\text{B}_2\text{O}_3$
Bisilicate	$\text{RO} \cdot \text{SiO}_2$	Metaborate	$\text{RO} \cdot \text{B}_2\text{O}_3$
Trisilicate	$2\text{RO} \cdot 3\text{SiO}_2$	Tetraborate	$\text{RO} \cdot 2\text{B}_2\text{O}_3$

sulfurous samples. Conversely, if the silica content is too high a viscous slag will result, preventing the collection of the PM and giving difficulty in pouring.

**Other agents** Fluorspar,  $\text{CaF}_2$ , melts at  $900^\circ\text{C}$  without dissociation. It is a neutral flux used to dissolve high-melting-point materials such as alumina, calcium phosphate, and barium compounds. A small amount may be added to any charge as it will aid in the separation of the button.

Sodium chloride volatilizes at red heat but it can be used to prevent dusting, exclude air, and wash down the sides of the crucible.

Lithium metaborate is useful in the assay of chromium-containing samples that do present particular difficulties and, as mentioned in earlier sections, litharge and nitre have fluxing properties.

**Temperature and furnace conditions** One of the commonest sources of error during pot fusion is poor mixing. It is essential, first, that the collector and reducing agent are intimately mixed and, second, that the sample is intimately mixed with these. This is best achieved by using a spatula and sulfite paper or by grinding them together in a mortar and pestle. Some assayers blend in the crucible with an iron rod. The fluxes can then be added, again ensuring a good mix. Finally, a covering of  $\text{NaCl}$  may be applied.

The furnace is brought to temperature (normally  $1000$ – $1200^\circ\text{C}$ ). Lead collections are normally run in the range  $1000$ – $1100^\circ\text{C}$  although temperatures as high as  $1300^\circ\text{C}$  may be used if alumina or baria ( $\text{BaO}$ ) are present. Nickel sulfide is run at  $\sim 1150^\circ\text{C}$  and copper at  $1250^\circ\text{C}$ . On charging the sample the temperature will fall to  $800$ – $900^\circ\text{C}$  and a very viscous melt forms that will help hold up the collector and give an efficient reaction. The temperature then rises again to the set temperature and the melt becomes fluid.

The time in the furnace will depend on whether it is a reducing (gas) fire or oxidizing (electrical) fire and on the sample size and type. For a lead collection of 25 g, 25–30 min is usually sufficient, increasing to 40–60 min for 100 g. Nickel sulfide runs take  $\sim 45$  min, and copper collection  $\sim 1$  h.

On completion of the melt the contents of the crucible are swirled to bring any unattacked material to the surface. If there is any residue in the crucible, it must be returned to the furnace to complete the fusion. Upon completion of the fusion the contents are poured into a lightly oiled iron mold, ensuring the collector goes into the mold apex and not down the sides. After cooling the slag is separated from the button and the slag retreated in the same crucible if appropriate. The button is physically cleaned of any

adhering slag and placed aside for the next stage of analysis. For nickel sulfide this will be grinding and chemical attack but for a lead button this could be any or all of scorification, cupellation, and a chemical attack, depending on the assay in question.

**Other considerations** There is no single, universal flux but the general flux referred to as ‘white flux’ can prove very useful. The composition is equal parts (by weight) of borax, sodium carbonate, potassium carbonate, and sodium chloride. This can be mixed and kept in bulk. Samples of 1–10 g are blended with 55 g of litharge and 5 g of fluor and 100 g of the white flux is added. This suffices for many materials of the sweep-type especially, and the addition of silica is unnecessary as corrosion of the crucible supplies all that is required to the fusion.

An obvious exception to the use of this type of flux is for sulfur-containing materials such as copper concentrates and, in the case of nickel sulfide, collection. Nickel sulfide is used when one is interested in PGMs rather than in gold and silver. The general type of charge is a sample of 20–50 g mixed intimately with 20 g of  $\text{NiO}$ , 12.5 g flowers of sulfur, and 10 g of silver sand placed in the crucible. The fluxes of 60 g of borax plus 30 g of sodium carbonate are placed on top and fused. The slag is rerun with a half-charge of collector and flux and the buttons combined for the ensuing analysis.

The charge for a copper collection is fairly standard, being:

- Sodium carbonate 80 g,
- Borax 40 g,
- Silver sand 12 g,
- Copper(I) oxide 50 g,
- Deactivated charcoal 2 g, and
- Sample 1–10 g.

Such a fusion gives a button of  $\sim 40$  g, but depends on the copper content of the sample.

### Scorification

This process is an oxidizing fusion and can be performed in two main areas.

It can be used as a replacement for pot fusion but is little used for accurate work. The sample, after oxidation, is mixed with lead, which acts as a collector and a fluxing agent. The sample is placed in a shallow impervious fireclay dish, covered with borax and placed in a furnace under an air draught. The lead is slowly oxidized to  $\text{PbO}$  with some being volatilized. During the fusion the borax reacts with the  $\text{PbO}$  to form a slag initially on the edges of the molten

charge. As the reaction proceeds the slag moves toward the center where the exposed lead forms an 'eye'. The scorifier is withdrawn from the furnace as the 'eye' closes and is poured into a mold as in pot fusion. This procedure can be useful for sulfides as the air decomposes the sulfide and the resulting oxide dissolves in the PbO.

The second and more widely used area of scorification is in the decrease in the size of lead buttons from pot fusion to a more manageable size whether they are going to be treated further by a chemical attack or cupellation (see below). This procedure will also be used if more than one button needs to be combined for subsequent operations. It proceeds in exactly the same manner as described above.

Bugbee gives a comprehensive description of this process.

### Cupellation

This is another oxidizing fusion that can be used in two main areas. The process is that a PM-containing lead button is placed on a cupel, which is essentially a shallow depression in a magnesia (MgO) or bone ash block.

The blocks are placed in a preheated furnace under an air draught; the lead melts and is oxidized. The molten PbO collects the non-PM-bearing part of the charge, small amounts of base metal oxide, and is absorbed into the porous cupel with ~1–2% being volatilized. A cupel can hold about its own weight in PbO. The PMs form a bead and due to their high surface tension are not absorbed.

The cupel is cooled, the PM bead removed, and taken for subsequent analysis. In some procedures the bead is simply weighed and a total PM content reported. This is generally used in mining laboratories where such results are sufficient for control purposes. In other procedures the bead is chemically analyzed to determine the individual PMs as required.

If gold is the element of interest then use is made of the 'parting' procedure. The bead is heated with nitric acid to dissolve away the silver, leaving the gold. In this case the Ag–Au weight ratio needs to be ~5:1 in order to obtain efficient parting. If the sample does not give this ratio then the inquartation method is used. This is the deliberate addition of silver at the cupellation stage to bring the ratio to the correct level for parting. The PGMs can impart a particular appearance to a silver bead. This is amply described by Bugbee. A very relevant practical point in cupellation is the cooling of the beads. Molten silver absorbs oxygen and if the cooling of the beads is not even there may be spitting, which gives the

beads small protuberances that may impair further processing or lead to losses.

The second cupellation procedure is used in the analysis of Dore bullion and fine gold alloys and bullion. In this case the sample has no preliminary fire assay and goes straight to the cupel. Generally, samples are of 0.5 g, weighed on a six-place balance. The sample is placed on lead foil along with ~0.1 g of copper wire to help carry away impurities and a piece of silver to give an Ag–Au weight ratio of ~2.5. These pieces can be prepared in bulk by cutting pieces of wire or sheet with a template. The lead foil is wrapped up as a small packet and the samples placed on preheated cupel blocks in a furnace at 1000°C.

The cupels are removed upon completion of the reaction, which can be monitored visually, the bead 'brightening' when the final thin layer of oxide has been absorbed.

The beads are then physically conditioned for parting. The bead is cleaned physically and tapped so that it can be rolled to a fairly long narrow strip. This is then coiled loosely and placed in a parting vessel. The silver is dissolved away by using, in turn, 1.16 relative density nitric acid, a boiling water wash, 1.284 relative density nitric acid, and a final wash to remove the acid. The resulting coils of gold, or cornets, are then dried, annealed to prevent them from breaking up, and weighed as gold.

With this procedure standards of 99.999% proof gold are included in the furnace run to cover the area of the furnace used. This is because there will be variations in each run and small gains may well be observed. The proof gold standard allows correction for these gains.

The accuracy obtained with this method is perhaps the highest of any analytical method one can use and is within 0.02% at very high levels of gold. For the analysis of fine gold at 99.99% the accuracy and precision will be better than 0.01%.

It is perhaps paradoxical in these days of high technology that one of the most accurate analyses carried out in the world originated in the time of the pharaohs with a basically unchanged methodology.

### Introduction

Flow analysis refers to quantitative analytical chemistry in flowing streams, and was devised in 1951 by L.T. Skeggs. The main driving forces for its inception and early development were the increasing demand for chemical assays at the Veterans Administration Hospital (Cleveland, OH, USA) and the consensus

that robotic systems at that time were too cumbersome to be practical. During development, it was realized that flow systems could play a wider role in laboratory automation and solution management, i.e., carrying out wet chemical analyses. Nowadays, the number of flow-based analytical methods, commercially available instruments, end users, and publications in the field continues to grow, demonstrating the worldwide acceptance of flow analysis. This article provides an overview of fundamentals, characteristics, flow analysis modes, theory, and applications.

### Fundamentals

Flow analysis is an approach to mechanized analytical chemistry usually carried out inside narrow bore tubing. An aliquot of an aqueous sample is

**Figure 1** Didactic presentation of a flow analyzer. S, sample; C, sample carrier stream; R, reagent stream; B, reactor; D, detector. For details, see text.

introduced into the flow system (see Figure 1), and pushed toward the detector by the carrier/wash stream. During transport through the analytical path, the sample undergoes dispersion and dilution, resulting in a well-defined sample zone that undergoes reproducible, online physical and chemical treatment, e.g., dilution, reagent addition, and dialysis. Sample passage through the detector results in a transient signal that is recorded as a peak, the height of which is proportional to the analyte concentration in the sample.

## Characteristics of the Flow System

### The Sample Volume Is Small

The sample aliquot is precisely selected (see Figure 1A), usually by means of either a loop-based or a time-based injection device. Typical sample volumes are 5–500  $\mu\text{L}$ , although volumes in the nanoliter range can be handled in microfluidic systems. Volume-limited samples such as biological fluids are therefore easily analyzed; *in vivo* assays are efficiently performed and operations such as dialysis, gas diffusion, and ion exchange are efficiently accomplished in-line. Reagent consumption is also low, typically 0.5–2.5  $\text{mL min}^{-1}$  per channel, thus

minimizing waste and allowing ‘environmentally friendly’ chemical analysis.

### The Analytical Path Is a Closed Environment

The selected sample volume is inserted into the flow system (see Figure 1B) and, while inside the analytical path, there is no physical contact of the sample with the external environment (and vice versa). Consequently, analyte losses and/or sample contamination, which lead to unreliable results, and environmental pollution, are avoided. The flow analyzer can therefore be regarded as a ‘clean room’ inside which the sample is manipulated under reproducible conditions. Drawbacks related to the use of hazardous and/or volatile reagents are also minimized.

### Dispersion/Dilution Is Inherent to Flow Analysis

During transport through the analytical path, the sample undergoes a continuous dispersion process and sudden dilution at the points where confluent streams are added (see Figure 1C), and control of these processes is a key parameter for system design. The degree of dispersion/dilution should be minimized when sample integrity needs to be preserved and increased when controlled sample dilution is needed in order to, e.g., match the dynamic range of the detector.

### Sample Passage Through the Analytical Path Is Fast

The mean sample residence time inside the analytical path is usually 10–180 s. As a consequence, some of the processes involved, e.g., derivatization, may not reach completion, allowing partial but reproducible development of chemical reactions, quantification of unstable chemical species, and easy implementation of catalytic methods. Flow-based procedures where chemical equilibria are not reached have often been proposed; this aspect should be considered with care however, particularly in relation to masking, which should always be quantitative.

Another feature arising from the short sample residence time is the feasibility of rapid and high throughput analysis, and this is relevant for process control, screening, and studies involving concentration-orientated feedback mechanisms. Alternatively, if a relatively long sample processing time is required, e.g., for procedures involving slow chemical reactions, specific strategies such as stream segmentation or sample stopping can be exploited.

### Sample Management Is Reproducible

Conditions for sample handling are reproducible from one sample to the next, and this feature is

particularly important for applications involving slurry processing, in-line sample digestion, exploitation of micellar media, monitoring of suspensions, and the use of renewable sensors. In some circumstances, e.g., in the analysis of sample batches with high variability in matrix composition, sample processing may not be reproducible from one sample to another. In such cases, the standard addition method or matrix matching procedures to circumvent matrix effects are easily implemented.

### The Analytical Signal Is Transient

When the processed sample passes through the detector, a transient modification of the monitored signal is obtained and is usually recorded as a peak (see Figure 1D). For most applications, the height (or area) of this peak is proportional to the analyte concentration and is the measured parameter. The detector is permanently situated in the flow manifold, thereby maintaining detection geometry during the analysis of entire sample batches, which leads to an improvement in repeatability. Moreover, monitoring the detector output in the presence (analytical signal) and absence (baseline) of the flowing sample is a useful diagnostic tool for assessing the proper operation of the system.

### Sample Throughput Is High

Flushing time, the interval between achievement of the maximum analytical signal and baseline restoration, is typically 12–120 s. The next sample can therefore be introduced without a long delay time and this permits a high sample throughput, typically 30–300 h<sup>-1</sup>. This is particularly advantageous in relation to, e.g., repetitive measurements, simultaneous determinations, titrations, standard additions, and quality control.

### Concentration Gradients Can Be Exploited

The recorded peak (see Figure 1E) represents an ‘infinite’ number of fluid elements in the flowing sample, each one associated with a particular mean sample residence time, and hence a particular condition for sample manipulation and a particular analyte concentration. A number of different analytical signals are therefore obtained during monitoring of the sample zone, allowing the easy implementation of analytical procedures involving exploitation of concentration gradients. To this end, algorithms for multiparametric analysis are generally used. Moreover, this permits the generation of an analytical curve using only one standard solution.

The concentration gradients established may also be undesirable, as they can impair measurement.

A typical example is the Schlieren effect arising from the presence of neighboring fluid elements with different compositions, and therefore refractive indices, which results in a myriad of ‘lenses’ and ‘mirrors’ randomly established inside the flowing sample. A common example of this is the introduction of a saline sample (high ionic strength) into an aqueous carrier stream. Occurrence of the Schlieren effect can limit the signal-to-noise ratio in some flow-based spectrophotometric procedures; it can be reduced and/or compensated by improving system design, exploiting matrix matching, and/or using a dual-wavelength spectrophotometer.

### A ‘Time Window’ Is Available

The mean available time intervals for the development of all the steps to which the sample is subjected are strictly constant because rigid timing control is inherent to flow analyzers. In view of this ‘time window’, the samples and reference solutions are manipulated under reproducible conditions, and this aspect leads to more precise results. Moreover, exploitation of this feature permits the easy implementation of analytical procedures even when analogous batch procedures do not exist.

Another favorable aspect inherent to flow-based analytical methods is that the possibility of random errors due to operator intervention is significantly reduced. Classical glassware, e.g., volumetric flasks, pipettes, funnels, and burettes, designed a century ago are less intensively used. Attention should be paid, however, to the possibility of systematic errors, which are generally increased when a traditional analytical procedure is carried out in a mechanized fashion. Regarding this aspect, detecting and circumventing potential sources of inaccuracy can be accomplished in-line.

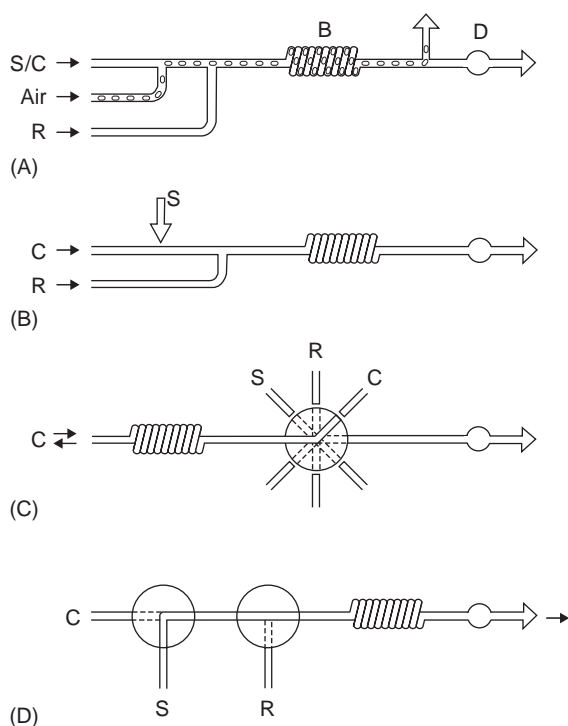

In addition to the above-mentioned aspects, the present trend toward full automation, miniaturization, and *in situ* analysis reflects the attractive characteristics of flow-based methodologies.

## Types of Flow Analysis

Flow analysis can be classified into three different types, each characterized by the distinct nature of the flowing streams, the versatility of the flow analyzer, and the degree of external control.

### Segmented Flow Analysis

In segmented flow analysis, either the sample or a wash solution is aspirated to merge with an air (or immiscible solvent) stream (see Figure 2A), resulting in a segmented stream comprising a number of

**Figure 2** Flow diagrams of different flow analyzers comprising only the sample, carrier, and reagent solutions. (A), (B), (C), (D) correspond to segmented flow, flow injection, sequential injection, and multi-commuted flow analyzers, respectively. Symbols as in **Figure 1**.

discrete plugs. As a consequence of stream segmentation, broadening of the sample zone (thus carry-over) is minimized, mixing conditions within each plug are improved, and the tubing inner walls are scrubbed. These favorable features are a consequence of the typical flow pattern inside the plugs (see **Figure 3**). The segmented sample zone is manipulated inside the analytical path under conditions of limited dispersion. As two phases are involved, sample manipulation is, however, somewhat restricted by compression/expansion phenomena (often temperature dependent) that can limit versatility and sample throughput.

The air phase is generally physically removed immediately before detection or, in modern analyzers, electronically removed with a bubble-gating device. A steady state situation is approached at the central portion of the monitored sample; therefore, the recorded peak is flat topped.

The initial development of air-segmented flow analysis (also known as CFA, from 'continuous flow analysis') was restricted to Technicon Corporation Inc., owner of the main patents until the mid-1970s. The first air-segmented systems were marketed in clinical chemistry with the AutoAnalyzer<sup>®</sup> trade

**Figure 3** Flow pattern of a segmented flow analyzer. Figure refers to a part of a coiled reactor encompassing a liquid segment between two of the successive gaseous bubbles. 1, Tubing wall; 2, thin liquid layer adherent to it; 3, movement inside the liquid phase; 4, gaseous bubble. Overall displacement is specified by the outer large arrow.

name. Expansion of the original CFA concept led to the appearance of multi-channel segmented flow analyzers, where several peaks (each for a different analyte) are simultaneously recorded per sample. In clinical chemistry, this multiple output represents the so-called 'multiple analysis chart', recognized as a very important tool for clinical diagnosis.

The dimensions of the analytical path cannot be reduced at will, as the bubble pattern has to be preserved. Moreover, a large sample volume is required in order to provide an almost steady-state situation at the center of the flowing sample zone. As a consequence of these features, reagent consumption is relatively high. As sample broadening is low, several samples are simultaneously manipulated inside the analytical path and this is important for achieving long sample residence times without impairing sample throughput. Passage of the sample zone through the pumping unit is also a drawback.

System operation is not very amenable to external control, as the only moving element in the flow analyzer is the sampler arm. This does, however, mean that such systems are rugged and reliable. Segmented flow analyzers played a dominant role in automated chemical assays for several decades and are still the basis for several commercial analyzers, particularly in clinical and environmental (water quality) laboratories.

### Unsegmented Flow Analysis

In this type, the sample is manipulated inside a continuously flowing unsegmented stream that acts as an incompressible and homogeneous column. This liquid column can be efficiently managed, allowing different processes such as stream splitting, stream redirecting, flow reversal, sample stopping, sample slicing, zone sampling, and merging zones to be easily accomplished. Consequently, system design is simplified, versatility is enhanced, and timing is more precise compared with segmented flow analyzers. As segmentation is not involved, a higher degree of external control can be attained, and hyphenation with other techniques is more efficiently accomplished. System miniaturization is easier with unsegmented flow analysis and has led to the appearance of microfluidic flow systems. These features are the main reasons for the rapid development and acceptance of unsegmented flow analysis, especially flow injection and sequential injection analysis.

Flow injection analysis was conceived in the mid-1970s independently by Ruzicka and Hansen and by Stewart *et al.*, who demonstrated the feasibility of sample injection into a continuously flowing unsegmented carrier stream for analytical purposes. The potential and versatility of so simple an analyzer amazed the scientific community. Since then, it has been by far the most investigated and applied unsegmented flow system, as demonstrated by more than 18 000 scientific articles and at least 12 manufacturers. In flow-injection analysis, the sample is inserted into an unsegmented carrier stream (often a reagent) and the established sample zone undergoes a continuous dispersion process, resulting in reproducible mixing of the sample with the carrier stream and, eventually, with other confluent streams (see **Figure 2B**). Control of sample dispersion/dilution enables its application to many different analytical methods. The recorded peak shape tends toward Gaussian in view of the efficiency of the dispersion process. Operation of the flow injection system relies on three cornerstones: sample injection, controlled dispersion, and reproducible timing. As flow is unsegmented, commutation (i.e., the ability to switch

fluidic zones between different channels) is an important feature of the flow injection analyzer and enhances versatility. Although manual operation of the system is possible, computer control is usually used.

Sequential injection analysis was proposed by Ruzicka and Marshall in 1990 as the answer to the increasing demand for system versatility and automation. In this system, a multiposition selection valve – the heart of the system – selects the sample and reagent aliquots to be sequentially aspirated, generating a stack of well-defined zones that is directed toward a holding coil. After a predefined time interval, the flow is reversed and the multi-position valve is switched in order to direct the stack toward the detector. During transport through the analytical path, the zones penetrate one another and mixing among them gives rise to the detectable species to be monitored. Versatility is an important characteristic of sequential injection analyzers, as several changes to the methodology can be achieved through software control of the system parameters rather than actual physical changes to the system architecture. Each port of the valve is dedicated to a specific purpose; therefore, combinations of sample, standards, reagents, sample treatment devices, and detectors around the valve are easily modified to suit a particular analysis.

### Zone Fluidics

This type encompasses a number of different concepts and variations of analyzers that have been developed as a logical consequence of the increasing presence of the computer in the laboratory, the need for enhanced versatility, and the diversity of applications demanding *in situ* (and often *in vivo*) assays. Such analyzers are usually small, lightweight, and portable. As a rule, they are also very versatile systems with a high degree of external control, involving both segmented and unsegmented (and also monosegmented) flows. Operation of discrete devices such as pumps, injectors, bidirectional valves, and multidirectional valves is usually controlled in real-time through feedback mechanisms. Batch injection analysis, bead injection analysis, discontinuous flow analysis, ‘lab-on-valve’, multisyringe flow analysis, and multi-commuted flow systems are examples of this type of flow analysis.

The multi-commuted system (see **Figure 2D**) is one of the most versatile systems, and exploits loop-based injection, time-based injection, or binary sampling for introducing the samples, reagents, and diluents in a programmable fashion. With discrete operation of its components, several approaches such as random reagent access, computer-controlled

splitting, multisite detection, and in-line sample preparation are efficiently accomplished. Zone fluidics (i.e., control and manipulation of flowing zones) is the underlying principle of this type of flow analyzer.

## Theoretical Aspects

Understanding how the sample zone interacts with the surrounding solution is of the utmost importance for system design and method implementation. In this regard, the flow regime – also alterations in flow pattern due to implementation of different strategies – and sample dispersion/dilution are key aspects to be considered.

### Flow Regime

In view of the typical flow rates and tubing dimensions of a flow analyzer, laminar flow is the prevailing regime, Reynolds number often being  $<2000$ . Laminarity has also been verified near confluence points where turbulence is more likely to occur.

Laminar flow in open tubes is characterized by the typical parabolic profile of the axial linear velocity distribution. Consequently, the linear velocity of a fluid element at the center of the tube is about twice the average linear flow velocity, whereas the linear velocity of the fluid elements near the tubing inner walls tends to zero. Therefore, after sample introduction, the chemical species in the frontal region of the sample zone, traveling at higher speed, diffuse toward less concentrated regions (and vice versa) whereas chemical species at the trailing edge, near the tube inner wall, diffuse toward faster moving central regions (and vice versa). This results in the so-called zone broadening effect with its deleterious influence on mixing conditions and, thus, sample throughput. In order to minimize this effect, different strategies such as segmentation (see Figure 3), reactor coiling, improvement in reactor design, and the use of supercritical flows have been proposed.

### Sample Dilution/Dispersion

A common feature of flow analysis is that during sample transport toward the detector, the combined effects of dilution and dispersion decrease the sample concentration, and the extent of these processes is very important for system design. Dilution occurs instantly at every confluence point due to mixing of the sample with the confluent stream. Under ideal mixing conditions, the concentration  $C$  of a chemical species in a fluid slice immediately before a confluence point is modified to  $C'$  according to

$$C' = C[N_1/(N_1 + N_2)] = C(N_1/N_3) \quad [1]$$

where  $N_1$ ,  $N_2$ , and  $N_3$  are flow rates of carrier, confluent, and resulting streams, respectively, the latter flowing at  $N_3$  [or  $(N_1 + N_2)$ ]. The enlargement of the sample zone by dispersion is also a consequence of confluent stream addition. These phenomena are often masked by downstream sample dispersion. Dilution predominates in segmented flow analysis and is also an important parameter in unsegmented flow systems with large sample volumes.

Dispersion occurs continuously during transport of the sample through the analytical path, due to the redistribution of material from the sample zone into the carrier stream, and is caused by convective and diffusive mass transport. Convective mass transport is a consequence of the parabolic distribution of the linear velocities of every fluid element, whereas diffusive mass transport is dependent on both the concentration differences between neighboring fluid elements and the diffusion coefficient. Although diffusive mass transport occurs in an isotropic fashion, only its radial component is relevant as a factor influencing dispersion inside a straight tubular reactor. Dispersion is an important parameter in unsegmented flow analysis, and can be efficiently controlled to give highly reproducible physical dispersion and hence reproducible analytical results. This effect is also relevant – although to a lesser extent – in segmented flow analysis, where the film of the solution established on the tube inner wall (see Figure 3) is the main source of carryover between successive segments. Dispersion can be experimentally manipulated by varying parameters such as sample volume, reactor geometry, and flow rates. Different models have been proposed for a quantitative description of sample dispersion in flow analysis and the convective–diffusive model (eqn [2]) has often been used to describe the concentration of any fluid element as a function of its spatial and temporal coordinates:

$$\begin{aligned} D_m(M^2C/Mx^2 + M^2C/Mr^2 + 1/rMC/Mr) \\ = MC/Mt + \Phi_0(1 - r^2/a^2)MC/Mx \end{aligned} \quad [2]$$

where  $D_m$  is the molecular diffusion coefficient,  $C$  the concentration of the specified fluid element,  $x$  the distance along the tube,  $r$  the radial distance from the tube axis,  $a$  the tube radius,  $t$  the time, and  $\Phi_0$  the maximum linear flow velocity at the center of the tube.

Equation [2] is derived from the mass balance in a differential volume of the fluid and considers the axial and radial concentration gradients as well as the linear velocities established in a laminar flow pattern in the absence of chemical reactions. The first term ( $M^2C/Mx^2$ ) refers to the axial diffusion and the other terms to the radial diffusion. The expression

$\Phi_0(1 - r^2/a^2)$  refers to the parabolic shape of the sample plug due to the different velocities of each fluid element. The expression  $MC/Mt$  refers to the temporal variation in concentration due solely to concentration gradients and is the main contribution to the very low sample dispersion occurring in situations where the flow is stopped. Equation [2] is presented in a differential fashion, so numerical calculations are required and boundary conditions need to be well defined in order to apply them to practical situations. This convective–diffusive model permits a quantitative description of sample dispersion in a flow analyzer, and provides a good simulation to assist further system design and method optimization. Equation [2] should be modified in order to consider the presence of reactors other than the open tubular reactor (e.g., coiled, knotted, packed bead), mixing chambers, micro-columns, and other specific devices in the analytical path. Other quantitative models have also been proposed for specific applications, particularly the tanks-in-series model for describing sample dilution/dispersion in relation to mixing chambers.

## Instrumentation

The flow analyzer involves simple apparatus such as samplers, liquid drivers (peristaltic pumps, piston pumps, solenoid pumps), injection devices (rotary valves, injector-commutators), reactors and flow lines (usually narrow bore tubing), mixing chambers, and flow-through detectors. As a rule, these devices are readily available in most laboratories devoted to chemical analysis. Regarding detection, almost all analytical techniques have been used in flow analysis; a small flow cell volume and a short response time that is compatible with system dynamics are important detector parameters.

## Applications

The number of applications in flow analysis is increasing, and several are related to modern concepts such as multi-commutation, multi-pumping, zone fluidics, and bead manipulation. This is perhaps the most important consequence of the favorable characteristics of the flow system, often leading to improved sample treatment and quantification.

Flow analysis is used mostly in fields characterized by a high demand for chemical assays; therefore, reported applications predominate in agronomic, environmental, geological, biomedical, and pharmaceutical areas, as well as industrial quality control. The notorious expression “My system processes a

number of samples but I only have a few” – the driving force toward the development of early flow analyzers – is sometimes no longer valid. In fact, there are situations where flow analysis is a viable solution for assaying a single sample.

Spectrophotometry and related techniques requiring intensive manipulations of liquid solutions are the most commonly used detection techniques in flow analysis because the flow analyzer is an excellent solution manager. Applications involving electro-analytical techniques, especially potentiometry and amperometry, have also been extensively reported. Techniques requiring sample monitoring under flowing conditions, e.g., atomic absorption/emission spectrometry (especially with hydride generation), flow enthalpimetry, and thermal lens spectrometry, as well as chemi- and bio-luminescence, are all enhanced by flow analysis as a means of online sample processing. There is also a trend toward using flow analysis in conjunction with online concentration/separation and with biosensors. Improved sample handling associated with flow analysis systems means that this family of techniques will continue to have a major impact on many application areas of Analytical Science.

## Introduction

Automatic methods applied to the analysis of series of samples can be grouped into three categories, namely batch, robotic, and continuous-flow methods. Flow injection (FI) methods fall into the last category. Although the first acronym for this technique was FIA, it was later shortened to FI both because rarely the overall analysis process is developed in an FI manifold and because FIA is the acronym used for fluoroimmunoassay. FI is a special mode of continuous analysis in which there are no bubbles separating the transport and/or reaction zones of samples successively introduced into the FI analyzer. Liquid samples (and, less commonly, solid or gaseous samples) are directly inserted into the dynamic system, along which they are carried and subjected or not subjected to one or more (bio)chemical reactions and/or separation processes. The dispersion or dilution of the analyte – or its reaction product – can be controlled through the geometric and dynamic features of the system. A continuous detector, usually furnished with a flow cell, is used to obtain transient signals. Neither physical equilibrium (homogenization of a portion of the flow) nor chemical equilibrium (reaction completeness) has been reached by the

time the signal is detected. Hence, FI methods can be regarded as fixed-time kinetic methods. Operational timing must always be highly reproducible because measurements are carried out under nonsteady physical and chemical conditions, so small changes may seriously affect the results obtained. In short, FI has four essential features: (1) unsegmented flow, (2) direct insertion, (3) controlled partial dispersion, and (4) reproducible operational timing.

This article provides an overview of this unsegmented flow technique. The units that make up an FI manifold and the basic analytical features are described. The types of recording and measurement provided by FI methods and the main similarities to and differences from other dynamic techniques are discussed, together with their theoretical and practical aspects. Elementary FI modes are briefly described in order to illustrate the versatility of this technique.

## The Basic FI System

A scheme of a basic FI manifold is shown in **Figure 1**. This consists of five main parts, namely:

1. The propulsion system, which establishes the flow at a rate as constant as possible of one or several solutions either containing dissolved reagents or merely acting as carriers. This function can be performed by a peristaltic pump (the propulsion system being more frequently used), a syringe or piston pump, a pressurized reservoir, a gravity-based unit, an electroosmotically pumped device, an osmotic pump, etc.

## Introduction

Automatic methods applied to the analysis of series of samples can be grouped into three categories, namely batch, robotic, and continuous-flow methods. Flow injection (FI) methods fall into the last category. Although the first acronym for this technique was FIA, it was later shortened to FI both because rarely the overall analysis process is developed in an FI manifold and because FIA is the acronym used for fluoroimmunoassay. FI is a special mode of continuous analysis in which there are no bubbles separating the transport and/or reaction zones of samples successively introduced into the FI analyzer. Liquid samples (and, less commonly, solid or gaseous samples) are directly inserted into the dynamic system, along which they are carried and subjected or not subjected to one or more (bio)chemical reactions and/or separation processes. The dispersion or dilution of the analyte – or its reaction product – can be controlled through the geometric and dynamic features of the system. A continuous detector, usually furnished with a flow cell, is used to obtain transient signals. Neither physical equilibrium (homogenization of a portion of the flow) nor chemical equilibrium (reaction completeness) has been reached by the

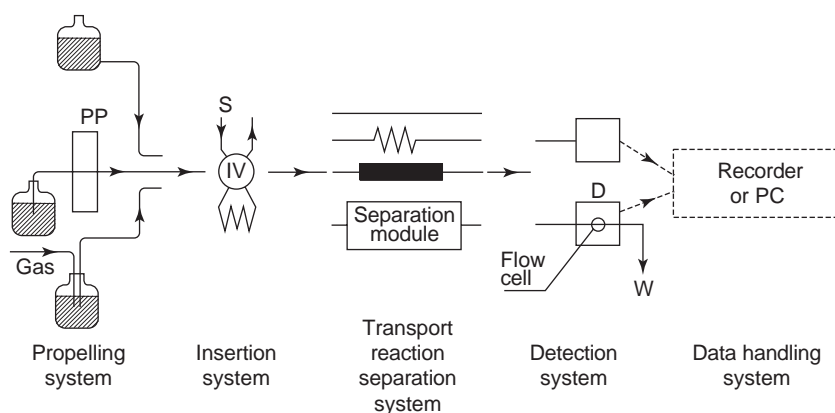

time the signal is detected. Hence, FI methods can be regarded as fixed-time kinetic methods. Operational timing must always be highly reproducible because measurements are carried out under nonsteady physical and chemical conditions, so small changes may seriously affect the results obtained. In short, FI has four essential features: (1) unsegmented flow, (2) direct insertion, (3) controlled partial dispersion, and (4) reproducible operational timing.

This article provides an overview of this unsegmented flow technique. The units that make up an FI manifold and the basic analytical features are described. The types of recording and measurement provided by FI methods and the main similarities to and differences from other dynamic techniques are discussed, together with their theoretical and practical aspects. Elementary FI modes are briefly described in order to illustrate the versatility of this technique.

## The Basic FI System

A scheme of a basic FI manifold is shown in **Figure 1**. This consists of five main parts, namely:

1. The propulsion system, which establishes the flow at a rate as constant as possible of one or several solutions either containing dissolved reagents or merely acting as carriers. This function can be performed by a peristaltic pump (the propulsion system being more frequently used), a syringe or piston pump, a pressurized reservoir, a gravity-based unit, an electroosmotically pumped device, an osmotic pump, etc.

**Figure 1** General scheme of an FI configuration. S denotes sample, PP peristaltic pump, IS injection system, D detector, W waste, and PC personal computer.

2. The sample introduction unit, which is usually an inexpensive low-pressure rotary valve that allows reproducible insertion of accurately measured sample microvolumes without the need for halting the flow – as in liquid chromatography (LC). Liquid samples can also be inserted by time-controlled aspiration at a merging point.

3. The transport–reaction system, which is often improperly called the ‘reactor’. This can be a straight, coiled, or knotted tube (0.3–0.8 mm i.d.), a length of tubing packed with a chemically active material (e.g., ion exchanger, sorbent material, redox reagent, an immobilized enzyme), a mini-mixing chamber, or separation module in which mass transfer across a gas–liquid, liquid–liquid, or solid–liquid interface takes place.

4. The detection system, which allows signals to be acquired and transduced as the analyte or the reacting plug passes through it. Nondestructive detectors such as spectroscopic (photometers, fluorimeters) and electrochemical detectors (potentiometric, voltammetric) use flow cells of various shapes and in different configurations, while destructive detectors (e.g., atomic spectrometric detectors) use no flow cell. The coupling of FI manifolds to high-resolution detectors such as Fourier-transform infrared and mass detectors is also possible.

5. The data acquisition system, a recorder or computer that receives the transduced signal from the detector.

The FI system can either be operated manually and the data acquisition performed by a recorder, or it can be readily automated to different degrees according to particular requirements. Presently, the integration of all the components of the FI manifold by an adequate software program is possible. All the

desirable functions can be controlled by a time- or an alert-based system.

In addition to the above essential elements, FI configurations may include other elements or some modifications of the basic units for developing special FI modes, generally to achieve special aims. Manipulation of the flow with a programmable propelling device – usually a peristaltic pump – can involve stopping the flow, changing the flow rate, changing the flow direction for passage of a given plug through the detection point as many times as required, precise measurements of the working time, etc., thus giving rise to approaches such as stopped-flow, iterative change of the flow direction, temporal variation of the flow rate, and time-based injection. Also, the possibilities for coupling rotary injection valves (in-series, in-parallel, interiorly) and the capability of their loops for holding different FI devices enhances the versatility of this technique.

The present trend toward miniaturization in modern analytical chemistry has affected FI in two main ways: (1) size reduction of the different units, especially tubing diameters; and (2) the design and commercialization of the so-called ‘integrated microconduits’, which include in a single plastic block smaller than a cigarette box almost the whole FI manifold (injection, reaction/transport, and detection units).

Notwithstanding the fact that FI is a relatively recent continuous-flow technique (the earliest reference to it appeared in 1975), it has gained widespread use, especially in the last decade, in which it has been the subject of a number of research papers, reviews, and monographs. However, despite its immense potential for routine analysis, FI has not yet been as widely commercialized or as greatly used as it deserves.

## Signal and Signal Measurement

When recorded, FI systems provide a transient signal, acquired by a detector on passage of the dispersed sample zone, which is similar to the signals provided by other analytical techniques such as chemiluminescence and electrothermal vaporization–atomic absorption spectrometry. A typical signal–time recording includes an abrupt rise from the baseline (see **Figure 2A**, in which the timescale is expanded). The most typical FI measurement is the peak height. However, gradient dilution techniques based on selecting a suitable element of the dispersed zone (usually at times longer than that of the maximum) are also used to obtain complementary information. The timescale of FI as used for routine monitoring is narrower and the signals obtained are similar to those shown in **Figure 2B**. These signals are yielded (1) by successive injections performed in order to construct a calibration graph (three injections per standard) and (2) by insertion of four identical microvolumes of sample. As can be seen, the reproducibility achieved is quite high, despite the typically kinetic, physical, and chemical, nature of the FI technique.

**Figure 2** Types of transient signals yielded by an FI system: (A) expanded conventional recording and measurement of the height at the maximum and at a time longer than that of the maximum (dilution mode); (B) usual recording for routine analyses (low chart speed).

The wide variety of FI applications developed so far provides a correspondingly wide variety of signals, the most outstanding of which are shown in **Figure 3**. The measurement parameters used in this context are also quite varied. Thus, in addition to the height, the area of an ordinary FI peak (**Figure 3A**) is also often related to the concentration, as in LC. The width at a given signal level (in time units) can also be related to the logarithm of the analyte concentration and permits calibrations to be performed at different sensitivity levels suited to the sample concentration, which is of great use to large-scale routine analyses.

The signals typically obtained by halting the flow when the reactant plug reaches the flow cell of a nondestructive detector (stopped-flow methods) allow signal increments ( $\Delta S$ ) to be measured throughout the standstill period and hence measurements of reaction rate to be obtained (**Figure 3B**). Because of their relative, rather than absolute, nature, such measurements are of particular use with catalytic methods employing dissolved enzymes and in avoiding interferences from sample matrices; however, they are only effective with slow analytical reactions (half-lives between 10 s and a few minutes).

The signals provided by retention(reaction)–detection systems are somewhat different from typical FI signals (**Figure 3C**). Retention is followed by elution and the signal includes an ordinary maximum that can be used to obtain the desired information. In addition, the slope of the rising portion of the signal is directly related to the analyte concentration.

FI multippeak recordings are provided by a variety of configurations including open–closed systems and those in which the iterative change of the flow direction causes the sample–reagent plug to pass many times through a nondestructive detector. Such signals provide richer information (**Figure 3D**). The sum of the signals from various peaks and the monitoring of the minima enables the calibration range be scaled up

**Figure 3** Type of measurements and recordings in FI systems: (A) peak height, peak area, or peak width at a preset height; (B) signal increment during the stop interval in the stopped-flow mode; (C) signal from flow-through sensors (measurement of the slope of the rising portion of the curve); (D) multippeak recordings from an FI system with iterative passage of the reactant plug through the detection point showing the different types of measurements. For details, see text.

or down, respectively, to suit each sample by using appropriate software and the same set of standards.

## FI versus LC, Segmented Continuous-Flow Analysis, and Sequential-Flow Analysis

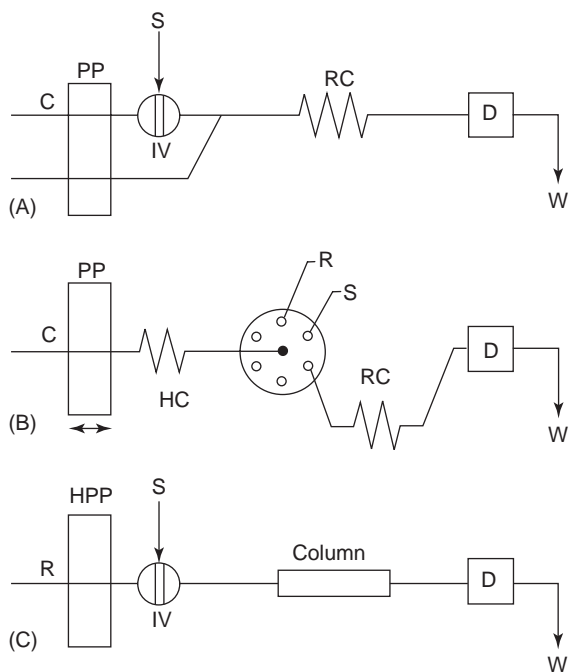

FI has some aspects in common with other dynamic techniques such as segmented continuous-flow systems (SCF), LC, and sequential-flow injection analysis (SIA). **Figure 4** highlights the similarities and differences between these techniques.

The most ostensible difference between SCF and FI lies in the absence of air bubbles in the latter, which are used in SCF to prevent carryover. This shortcoming is overcome in FI by the special geometric (small diameter of the tubing) and dynamic conditions (laminar flow). The absence of air bubbles in FI results in major advantages such as the ability to introduce reproducible sample volumes into the system by injection, reproducible handling with little pulsation, no requirement for predetector bubble separator, the possibility of reproducibly controlling the flow rate of the carrier and reagent streams (including preset intermittent stop and go periods), and that of including improved separation steps. Other outstanding differences lie in the lack of physical and chemical equilibria in FI, which enables kinetic

discrimination, measurement of transient or metastable species, and, in general, the development of methods unfeasible by SCF.

In relation to LC, FI has the following significant similarities and differences: the similarities include miniaturization capability, injection, unsegmented flow, small sample volume, signal profile, and the fact that both lack the characteristic lag phase of SFC. The most important difference between the two techniques probably lies on their foundation: in LC there is always an interface that affects the separation of a mixture of substances passing through the column. Other differences include the working pressure, which is low in FI, and sufficiently high in LC for the pump to overcome the dynamic resistance of the column. Also, the scope of application of the two techniques is very different since the basic aim of an LC instrument is to separate and analyse a complex mixture of substances, whereas the aim of FI is the rapid determination of one or two species in a large number of samples.

SIA, conceived as a single pump, single valve (frequently selection valve), single channel technique, was introduced as a feasible and mechanically simpler alternative to FI. Although SIA is based on the same principles as FI, the differences between these techniques are remarkable, especially when considering the dispersion patterns inside the two systems. In FI, reagents are normally added to the injected sample zone through confluence points, resulting in a concentration gradient of analyte within a constant background of reagent. In SIA, an initial sharp boundary is formed between the adjacent sample/reagent zones stacked in the holding coil; even after flow reversal, only a partial overlap of the analyte and reagent zones is achieved in these systems.

**Figure 4** Schemes of the common (continuous line) and uncommon parts (dotted line) of an FI manifold (A) as compared with an SIA system (B) and a chromatograph (C).

## Dispersion in FI Systems

### Types of Dispersion and Operational Modes

Theoretical studies on the FI technique have so far been aimed at defining the dispersion and dilution undergone by a sample plug on injection into an FI system, which ultimately defines the profile of the transient signal obtained and coincides with the dispersion at the detection point (flow cell). A number of authors have sought mathematical relationships between the basic parameters of an FI peak (travel or residence time, coordinates of the maximum, width) and the experimental features of the FI system, both of dynamic (flow rate) and of geometric nature (length, diameters of tubing, connectors, etc.). Despite of the endeavors made in this respect, no generic expressions for such potential relationships

have so far been obtained. A detailed description of the mathematical aspects of FI is provided in the monographs by Ruzicka and Hansen, and by Valcárcel and Luque de Castro. The most solid conclusions in this respect are summarized below:

1. Most FI systems operate under laminar-flow conditions, even though the limited carry-over or rather lack of it between successively injected samples was formerly ascribed to the occurrence of a turbulent regime.
2. The dispersion of the injected sample is a function, among others, of the time taken in the transport process. Initially, dilution is chiefly convective in nature; later, it becomes convective–diffusional and, finally, takes on purely diffusional character. The intermediate situation (i.e., convective–diffusional transport) is by far the most common in FI.
3. Radial dispersion contributes more significantly to the peak profile (dilution of the sample plug) than does axial dispersion. This type of fluid motion results in a washout effect accounting for the small carry-over between successively injected samples. This advantageous phenomenon in turn is a result of the use of low flow rates and small tubing bores, and leads to decreased peak widths and hence increased sample throughputs.
4. A number of theoretical approximations have been applied to the typical non-Gaussian shape of FI peaks, such as Taylor's and the tanks-in-series and mixing-chambers models. However, the most accurate description of the behavior of a solute injected into an FI system is provided by the so-called 'general model', which is based on a general equation describing convective–diffusional transport and takes account both axial and radial concentration gradients, the contribution of convective transport, and the parabolic shape of the velocity profile of a laminar-flow regime:

$$D \left[ \frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial r^2} + \frac{1}{r} \frac{\partial^2 C}{\partial r} \right] = \frac{\partial C}{\partial t} + u_0 \left[ 1 - \frac{r^2}{a^2} \right] \frac{\partial C}{\partial x}$$

where  $D$  is the molecular diffusion coefficient ( $\text{cm}^2 \text{s}^{-1}$ ),  $C$  is the analyte concentration,  $t$  is the time (s),  $x$  the distance along the tube,  $r$  is the tube radius (cm), and  $u_0$  is the linear flow velocity ( $\text{cm s}^{-1}$ ). This equation is far from easy to solve and requires the use of approximations that vary from author to author.

### Factors Affecting Dispersion

Dispersion in an FI manifold can be roughly modified by acting on the (1) dynamic or (2) geometric

variables, or (3) by modifying the kinetics of the biochemical reactions involved.

1. Provided other variables are constant, dispersion increases with decreased flow rate, which also increases the residence time of the plug in the continuous-flow system. Conversely, increased flow rates in the normal working range of FI ( $0.5\text{--}5 \text{ ml min}^{-1}$ ) decrease dispersion concurrently with increased sensitivity, as the height of the peak increases.
2. An increase in the reactor length has a similar effect on dispersion to that of decrease in the flow rate because both parameters have a similar influence on the residence time. However, the dispersion can be greatly altered by changing the geometric form of the reactor. Possible reactor geometries are shown in **Figure 5**. Dispersion decreases from (A) to (D) as an additional 'secondary flow' occurs which increases the radial dispersion in nonstraight tubes. This effect increases with the length traveled by the plug, and as a result the sensitivity also increases. Also, decreasing the inner diameter of the tube results in decreasing dispersion because of the increasing occurrence of secondary flow. On the other hand, inclusion of a mini-mixing chamber in a continuous-flow system increases dispersion and increases the difference between the height of the signal recorded in the absence of dispersion (obtained by aspirating the sample instead of the carrier) and the maximum of the FI peak:

$$D_{\text{max}} = h_0/h_{\text{max}}$$

By definition,  $D$  will always be greater than unity, unless the system incorporated facilities for preconcentration. In routine FI applications,  $D_{\text{max}}$  ranges between 1 and 15. As  $D$  increases, the resulting FI

**Figure 5** Reactor geometries most frequently used in FI: (A) straight open tube; (B) coiled tube; (C) knotted reactor; and (D) single bead string reactor.

peak becomes flatter, even though the enclosed area remains constant. The larger the  $D$  is, the lower will be the sensitivity achieved if the maximum height is used as measurement parameter. The sample throughput also decreases with increasing  $D$ , which results in increased peak width and hence in a higher risk of peak overlap. This is a clear symptom of undesirable carryover between samples.

## General FI Modes

Single-channel manifolds are used when no chemical reactions are required prior to detection (e.g., use of electrochemical or atomic spectroscopic detectors). However, even in these cases, some treatments or conditioning makes it necessary to use additional channels. Thus, from the most basic FI system (Figure 1) setups can vary widely depending on the chemical system involved and/or the particular aim. Some of the more elementary FI modes deriving from the basic scheme are illustrated in Figure 6 and described below.

### Multichannel Manifolds

Two channels merging before the injection system can be required to generate a reagent in *status nascenti* or to obtain a reaction medium in which the reagent is unstable (Figure 6A). Other additional merging channels can be required for masking purposes and/or to sequentially develop the different steps of an overall reaction (Figure 6B).

### Reversed FI

The roles of sample and reagent can be exchanged in an FI manifold (Figure 6C). This reversal is particularly useful when the sample is abundant and inexpensive (e.g., drinking- or wastewater), as it saves reagent. The sequential determination of several analytes can be accomplished by inserting into the sample channel as many injection valves as required, through which selective reagents for different analytes can be inserted into the sample stream (Figure 6D).

### Merging-Zone Mode

This approach allows saving both the sample and the reagent. A dual-injection system is used to inject the sample and the reagent simultaneously into two carriers or additional reagent streams (Figure 6E). The length ratio of the channels between the injection and merging points give rise to two merging-zone modes: the symmetric mode, when both channels have the same length and both injected plugs merge completely (Figure 6F); and the asymmetric mode (the

most versatile), which requires different sample and reagent volumes in addition to different lengths of the channels between the injection and merging points in order to ensure mixing of the sample with the carrier, or an additional reagent stream on one of its ends with the injected reagent on the other (Figure 6G). In this way, it is possible to develop simultaneous determinations of two analytes.

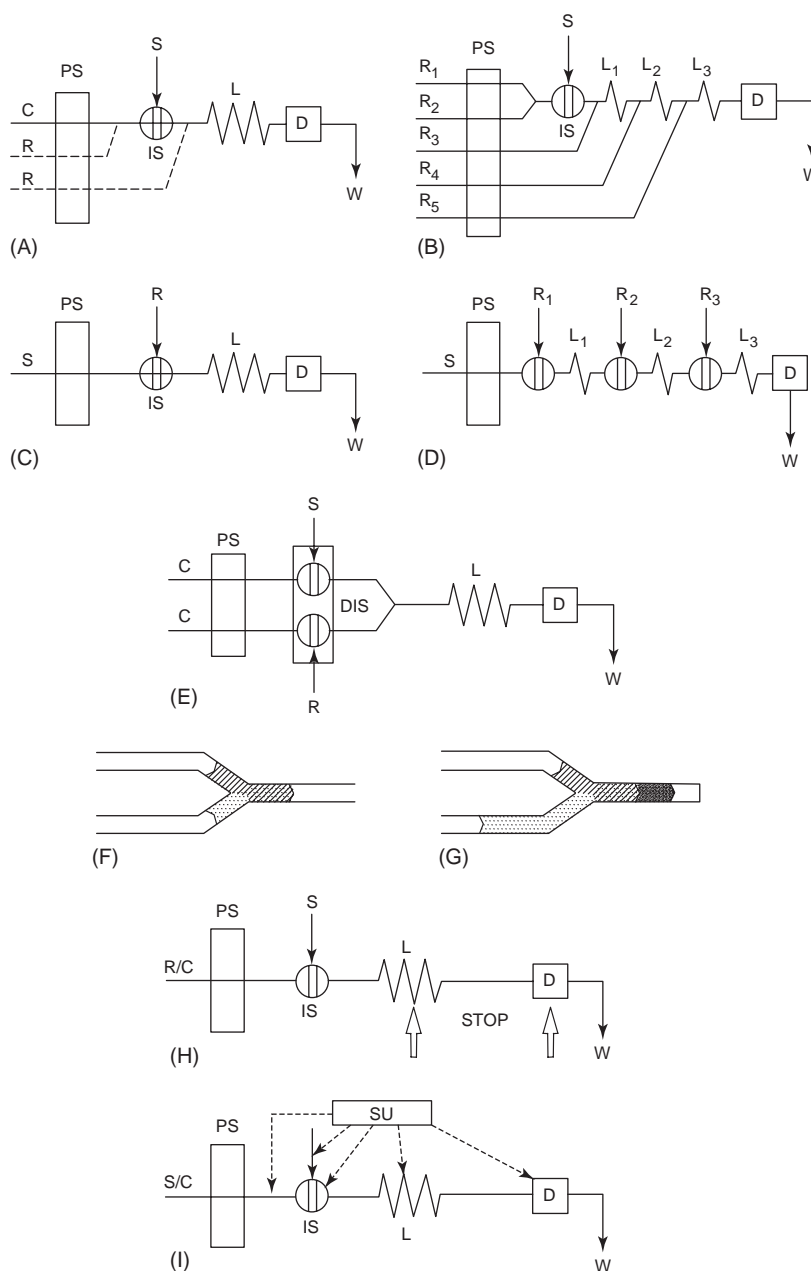

### Stopped-Flow Mode

By synchronizing the propulsion and the injection systems through a timer or microcomputer (Figure 6H), the flow can be halted when the injected plug reaches a preset zone of the manifold. Most commonly, the injected plug is stopped at the flow cell in order to monitor the development of a biochemical reaction between the analyte in the sample and some reagent contained in the carrier or merged with the main channel prior to the detection point. In this way, it is possible to perform reaction rate measurements. However, the flow can also be halted while the reacting plug is in the reactor, thus allowing a longer sample–reagent contact time prior to measurement.

### Inline Coupling with Nonchromatographic Continuous Separation Techniques

Enhanced sensitivity (through a preconcentration step) and/or selectivity (by removing interferences from the sample matrix or, less commonly, from reagents) can be achieved by using a nonchromatographic continuous separation technique/flow injection arrangement. Nonchromatographic separation techniques involving all types of interfaces (gas–liquid, liquid–liquid, and solid–liquid) can be coupled inline to FI manifolds at locations depending on the pursued aim (Figure 6I): placing the separation unit in the main channel prior to injection is intended to effect reagent purification, while placement in the sample stream, in the injection system or between this and the detector, is aimed at preconcentration and/or interference removal. Finally, if the separation unit is in the flow cell, integration of separation and detection usually provides increased sensitivity and selectivity by *in situ* concentration and kinetic monitoring of the separation process, respectively.

Nonchromatographic continuous separation techniques involving gas–liquid interfaces (e.g., gas diffusion, hydride generation, pervaporation) prior to detection by an atomic spectrometer have frequently been coupled to FI manifolds to develop excellent methods of interest, mainly to the clinical and industrial fields.

**Figure 6** Elementary FI modes: (A) and (B) multichannel manifolds; (C) and (D) reversed mode; (E) merging-zone manifold; symmetric (F) and unsymmetric (G) merging patterns; (H) stopped-flow mode; (I) possible locations of a separation unit in an FI manifold. C denotes carrier, R reagent, PS propulsion system, S sample, IS injection system, L reactor, D detector, W waste, DIS dual-injection system, and SU separation unit.

Liquid–liquid interfaces have been involved in FI configurations mainly through dialysis and extraction. Excellent yields are obtained through the separation process as the FI manifold can be altered to match the performance of the method concerned to the features of the sample and/or analyte to be determined.

Ion exchange and sorption systems in general are the most common types of nonchromatographic

continuous separation techniques involving liquid–solid interfaces that have been coupled to FI. In addition to the dramatic enhancement in sensitivity and/or selectivity achieved inline by using microcolumns of an active material, the ease with which they can be included in FI systems has fostered their usage in virtually all fields of applied analysis. Also, unconventional liquid–solid separation techniques such as stripping techniques have been successfully

implemented in FI systems as their development in a continuous fashion circumvents many of the shortcomings involved in batch stripping methods. Typically, manual liquid–solid separation processes, such as those involving precipitation/filtration/dissolution, have also been implemented in continuous FI manifolds, thus allowing automation of these conventional, tedious procedures.

### Online Coupling with Chromatographic Separation Techniques and Capillary Electrophoresis

The coupling of an FI system to a liquid chromatograph in a pre- or postcolumn arrangement saves reagents when derivatizing reactions are required either for facilitating the chromatographic separation or for detection. In addition, the sensitivity can be matched to particular requirements.

The coupling of an FI manifold to capillary electrophoresis equipment enables sample preparation prior to introduction into the capillary. FI preconcentration by liquid–solid steps, dialysis, and liquid–liquid separations have been developed in a precapillary position.

### Basic Analytical Features of FI

A comparison of the main analytical features of FI with those of its sequential injection and manual counterparts highlights its advantages and disadvantages.

Two typical features of FI methods are: (1) the reaction time is rather short, so equilibrium is not attained; and (2) the physical dispersion or dilution of the sample in the carrier results in a signal of lower intensity than that corresponding to the undiluted plug. However, the dispersion pattern inside an FI system results in a concentration gradient of analyte within a constant background of reagent; in an SI system the initial sharp boundary formed between the adjacent sample/reagent zones stacked in the holding coil, and even after the flow reversal, only a partial overlap of analyte and reagent is achieved. This fact gives rise to lower dispersion, but it is also a source of inaccuracy, especially when the sample is contaminated with interferents.

The lower sensitivity of FI is amply offset by its versatility, which allows sensitivity to be decreased or enhanced at will. A decrease in sensitivity can be achieved by decreasing the flow rate or injected volume, increasing the length of the reactor or using auxiliary channels, using under-optimal chemical conditions, or performing measurements at points far from the maximum of the FI peak. The different ways of enhancing sensitivity in FI can be classified into three groups: (1) by altering the FI manifold or

the working conditions (using large sample volumes, increasing the residence time without increasing the dispersion by stopping the flow in the reactor, reducing tubing diameters, using solid reagents, or introduction of membrane-based reagents or using micellar media); (2) by inline coupling with a separation/preconcentration technique (any of those described above) and by using integrated separation/detection approaches; and (3) by using the so-called ‘scale expansion techniques’, based on chemometrics, which allow calibration curves to be expanded at either end.

Enhanced selectivity is usually achieved when either a manual or air-segmented method is adapted to FI as a result of its kinetic nature: unwanted reactions do not develop to a significant extent over the short residence times of FI methods. Another positive aspect of FI is that the use of a closed system inherent in the technique prevents reagents and sample from coming into contact with the atmosphere, thereby avoiding undesirable reactions with air components.

Although FI involves kinetic, physical, and chemical aspects which may *a priori* lead readers to conclude that results will not be too good in terms of precision, the reproducibility is comparable to, or better than, that of SI and manual methods, which is probably one of the reasons of the success of this methodology. This feature makes FI methods reliable for use in intercomparison studies.

Rapidity is one of the most outstanding features of FI methods, which are usually much faster than their manual and automatic counterparts. The time spent in tuning an FI system is similar to that of an SI system because the 5–10 min required for injection depends on the time required by the propulsion system for regulating the flow. As a rule, the start-up time is dictated by the warm-up time of the detector. However, the rapidity of FI is apparent in the sample rate or frequency, which is higher than that of manual and SI. Finally, when a multisyringe approach is used, this is limited by the necessity of reloading the syringes after each cycle. Nevertheless, the sampling frequency of FI methods strongly depends on the kinetics of the chemical reaction as an acceptable amount of the monitored product is needed to ensure appropriate sensitivity.

Simplicity is also a salient feature of both FI and SI, and arises from their simple foundation: the experimental arrangements are simple, in clear contrast to the new analytical methodologies; and they are systems of easy design and operation.

As FI and SI share the same principles (precise sample introduction, controlled dispersion, and reproducible timing), the costs are very similar and lower than those of commercial analyzers providing a similar (or even poorer) performance. For the same reason, the

versatility provided by both is according to the modular nature that allows them to meet a wide variety of analytical needs. Nevertheless, the highest versatility of FI is clearly demonstrated in the widest number of modes it is capable of implementing, most of them are unable to be implemented by the SI technique.

## Introduction

One of the key features of flow injection (FI), in addition to its versatility and simplicity, is its low cost. The cost is low partly because the working pressures used in FI methods are usually lower than 70 kPa (~10 psi), which means that the different units making up the FI manifolds are easy to design and inexpensive to assemble. Although several FI instruments are already commercially available, the individual basic and dedicated components needed to construct FI equipment can be purchased separately. This is especially useful in those cases where innovations are intended.

The basic units of an FI manifold – the propulsion, reaction, and detection/data acquisition systems – are described in detail together with the most salient types and modifications of the propulsion, injection, and reaction units. Details are also given of other units that can sometimes be dispensed with, but are commonly used in the implementation of a variety of FI methods, especially in connection with rather complex samples. These special components may be

separation/preconcentration units (gas diffusers, pervaporators, dialyzers, liquid–liquid extractors, etc.), mini-mixing chambers, special valves, etc., in addition to the elements required for full or partial automation of an FI analyzer, namely samplers and interfaces.

## Basic Units

Three essential components of an FI system are shown in **Figure 1**, which also shows different possible modifications, simple or complex, that could be made depending on the problem to be solved. The fourth essential unit – the detector – is not part of FI manifolds, as it can be coupled to any type of molecular detector – provided the appropriate flow cell is available – or atomic detector.

## Propulsion Units

One of the most outstanding features of FI – versatility – is partially supported on the propelling unit. The requirements for an ideal functioning of this unit in FI may be summarized as follows:

1. Reproducible flow rates on a short- (hours) or long-term (days) basis, in order to provide a predictable residence time and a constant dispersion (directly related to the flow rate) throughout the manifold.

versatility provided by both is according to the modular nature that allows them to meet a wide variety of analytical needs. Nevertheless, the highest versatility of FI is clearly demonstrated in the widest number of modes it is capable of implementing, most of them are unable to be implemented by the SI technique.

## Introduction

One of the key features of flow injection (FI), in addition to its versatility and simplicity, is its low cost. The cost is low partly because the working pressures used in FI methods are usually lower than 70 kPa (~10 psi), which means that the different units making up the FI manifolds are easy to design and inexpensive to assemble. Although several FI instruments are already commercially available, the individual basic and dedicated components needed to construct FI equipment can be purchased separately. This is especially useful in those cases where innovations are intended.

The basic units of an FI manifold – the propulsion, reaction, and detection/data acquisition systems – are described in detail together with the most salient types and modifications of the propulsion, injection, and reaction units. Details are also given of other units that can sometimes be dispensed with, but are commonly used in the implementation of a variety of FI methods, especially in connection with rather complex samples. These special components may be

separation/preconcentration units (gas diffusers, pervaporators, dialyzers, liquid–liquid extractors, etc.), mini-mixing chambers, special valves, etc., in addition to the elements required for full or partial automation of an FI analyzer, namely samplers and interfaces.

## Basic Units

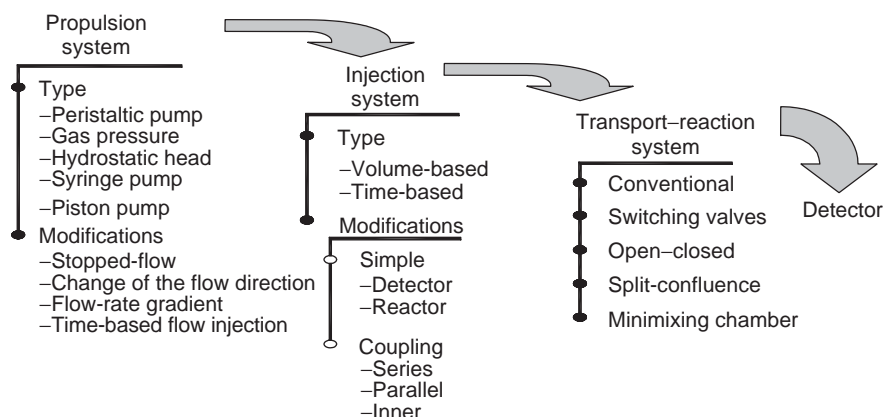

Three essential components of an FI system are shown in **Figure 1**, which also shows different possible modifications, simple or complex, that could be made depending on the problem to be solved. The fourth essential unit – the detector – is not part of FI manifolds, as it can be coupled to any type of molecular detector – provided the appropriate flow cell is available – or atomic detector.

## Propulsion Units

One of the most outstanding features of FI – versatility – is partially supported on the propelling unit. The requirements for an ideal functioning of this unit in FI may be summarized as follows:

1. Reproducible flow rates on a short- (hours) or long-term (days) basis, in order to provide a predictable residence time and a constant dispersion (directly related to the flow rate) throughout the manifold.

**Figure 1** Basic units of a flow injection manifold and possible modifications.

2. Multichannel capability for providing at least four parallel streams to ensure versatility.
3. Pulse-free flow that is not completely fulfilled in commercially available propelling systems but can be avoided by using a suitable attenuator.
4. Resistance to aggressive reagents and solvents.
5. Readily adjustable flow rates, and low initial investment and running cost.

A large variety of these devices have been used but, unfortunately, none of them meets all the requirements listed above. One way to minimize the limitations of the propelling systems is by computer-controlled flow programming. Also, it is possible to reach ideal conditions under specific circumstances where some of the requirements are not critical, or by a combination of different propelling units.

A distinctive feature of the propelling devices in FI systems is the low working pressure required for obtaining suitable flow rates. FI systems usually operate at pressures lower than 10 psi. When higher working pressures are required for special applications, high-performance liquid chromatography (HPLC) pumps can be used.

The usual location of the propelling unit is before the injection system. However, in some FI systems the propelling unit is placed after the detection system, to probably achieve improved pulse attenuation.

The general trend toward miniaturization in all branches of science can also be seen in propelling units. In addition to easier transportation of micro-propelling devices, especially those required in portable and submersible FI analyzers, other advantages afforded are low reagent and sample consumption, fast sample–reagent mixing, and decreased undesired broadening of the sample zone, thus increasing both sampling frequency and sensitivity. However,

**Figure 2** Details of the drum of a peristaltic pump showing the rollers squeezing the flexible tubing.

limitations such as power requirements and periodic replacement of some elements (tubes, usually) are needed when they are operating in a continuous mode.

The propelling systems normally used in FI are peristaltic, piston, syringe, and solenoid pumps, gravity-driven sources, electro-osmotic flow (EOF) devices, and osmotic pumps.

Peristaltic pumps are the ones most commonly used in FI. They consist of a motor-driven wheel with peripheral placed rollers and an adjustable compression cam (or band) that is squeezed against the rollers (**Figure 2**). The successive peristaltic movements of the tubes force various fluids through the tubes. The number of channels depends on the roller length and usually ranges from 1 to 16. Pump tubes are made of poly(vinyl chloride) (PVC), silicone, or any other similar plastic material. Two collars are usually glued near the end of each pump tube with a dual purpose: first, to serve as a point of attachment between the

harnesses of the pump and, second, to identify the inner diameter and hence the flow rate. Tygon<sup>®</sup> tubes are used to propel aqueous solutions and alcoholic solutions, wherein the alcohol content should not exceed 5% in order to ensure a long tube lifetime. Strongly acidic or basic solutions should be pumped through other tubes made from other materials. Thus, Solvaflex<sup>®</sup> yellow pump tubes are used to propel alcoholic solutions and some alkanes. Also, pump tubes made from Viton material are used to propel strong acidic solutions and some chlorinated organic solvents.

According to the preferable usage pattern of peristaltic pumps in FI, major changes have been introduced in them. Peristaltic pumps usually work in one direction and at a constant flow rate. Any change in some characteristic requires appropriate programming. By increasing computerization in the laboratory environment, new FI methodologies have evolved on pump functioning: stopped-flow, iterative change of the flow direction, flow variation as a function of time, time-based injection, etc. Start-and-stop, variable pump speed, and forward-backward flow direction are some modes in which these devices work. Also, improvements in the performance of peristaltic pumps have been aimed at exploiting flow pulsation for increasing sensitivity in voltammetric detection and improving both sensitivity and selectivity in atomic detection. Strategies for injection/pumping synchronization have also been exploited both for improving measurement precision and providing scope for new FI approaches.

In addition to peristaltic pumps, other propelling devices have been used in FI. Syringe pumps are durable devices and capable of generating a pulse-free, perfectly controlled flow. However, they are too expensive to be used in multireagent systems and their less expensive versions (such as infusion pumps) are not designed to stop or reverse the flow precisely enough. Piston pumps operate by moving the plunger (piston) back and forth in a pump head, and using one-way directional check valves (usually ball-style valves). The movements produced by the rotation of a circular cam provide a pipeline flow-rate diagram and, therefore, provide changes in pumping speed. This makes it less readily adapted to FI requirements, as they are usually designed for use in HPLC. Solenoid pumps operate by the same mechanism as piston pumps with the only difference that the movements are produced by a diaphragm, usually made from polyether ether ketone (PEEK) and Viton. Some miniaturized solenoid pumps can replace peristaltic pumps for *in situ* applications to minimize size, weight, maintenance, and power requirements. Gas-pressurized reservoirs are simple, inexpensive, do

not contain any moving parts, and produce pulseless flow. However, it is very difficult to adjust the flow rate in a multiple line manifold. Gravity-based propelling units rely on the difference in height between the reagent and/or carrier reservoir and the FI line. A pulse-free flow is obtained and the different heights determine the flow rate. The most significant shortcoming is the need for maintaining a constant level of the liquid(s) in the reservoir(s). EOF-based pumps are made of materials whose surfaces can carry a net charge when in contact with aqueous solutions. The oppositely charged counterions present in the aqueous solutions are attracted by these surfaces. Application of an external electric field results in a net migration of these counterions toward the oppositely charged electrodes. The major application of EOF propelling systems is in capillary dynamic systems. Analyte enrichment, limited dispersion, and removal of matrix interferences are remarkable features of EOF systems. Osmotic pumps provide a flow by the osmotic pressure created across a rigid semipermeable membrane separating a saturated salt solution from a solution of lower salinity. The diffusion of water through the membrane results in a net flow from the diluted to more saline solution. Temperature dependence and low flow rates reduce the usage of these propelling units in FI.

### Injection Systems

The injection system is intended to insert a well-defined plug into the flowing carrier stream and should meet a number of requirements imposed by the intrinsic features of the FI technique, namely:

1. It should introduce accurately measured volumes (usually within 25–100  $\mu\text{l}$ ) of a sample or reagent in a reproducible manner. The wider the volume range, the more versatile the system.
2. The sample should be incorporated into the carrier stream in such a way that no disturbances are caused to the latter.
3. It should allow for convenient and fast operation in order to provide a high sampling rate.

In addition, it should be controllable by an electric motor. The injection devices designed for this purpose can be divided into the following categories: volume-based injectors, time-based injectors, or a combination of these two. The first type of device is based on the typical entrapment of the sample solution into a geometrically well-defined volumetric cavity and subsequent transfer (injection) of the sample zone thus formed in the unsegmented carrier stream. The second category is based on the

aspiration of the sample solution at a constant flow rate for a fixed period of time into a well-defined section of a flow-through channel from which the metered sample solution is injected into the carrier stream by a combination of hydrostatic and hydrodynamic forces. Whereas in time-based injection procedures a crucial role is the control of the injection volume by the selected time interval existing – and thus, the possibility of computer control – in volumetric methods, the sample volume is changed physically by changing the volume dimensions of the sample loop.

The injection unit first employed in FI was a syringe and a hypodermic needle. The injection system most frequently used now is a volume-based injection unit such as the typical six-port rotary valve shown in **Figure 3**. In the fill position, the sample (or reagents) enters the valve through port 2, fills the loop between ports 1 and 4, and goes to waste through port 3. Meanwhile, the carrier stream enters the valve through port 6 and passes out through port 5. In the inject position, port 6, through which the carrier enters the valve, is connected internally with port 1, sweeping the sample plug toward the detector through ports 4 and 5, while the sample flows into the valve through port 2 and is sent to waste through port 3. This type of valve gives high reproducibility in the injected volume, a wide range of variation in the loop volume, rapidity, and easy manual operation; in addition, it can be readily automated.

**Figure 3** Typical six-port rotary injection valve: (A) fill position and (B) inject position.

The facility for manipulating injection devices has multiplied their use, not only for such simple injection devices, but also for multiple injection approaches for fulfilling the different purposes of use. Some of the most common modifications and arrangements are shown in **Figure 4**. In addition to their use for single injection, their loops can hold the most varied flow devices (**Figure 4A**); they can be coupled in series (**Figure 4B**), in parallel (**Figure 4C**), and interiorly (**Figure 4D**). Even several of these couplings can be included in a single manifold, thus enlarging the number of steps to be developed in a single, cheap, and simple approach. The most salient of these approaches can be divided into two: use of a single injection valve and use of multiple injection valves, in the same manifold.

**Figure 4** Modifications of rotary valves: (A) inclusion of a flow cell or solid reactor in the loop; (B) serial and (C) parallel arrangements; and (D) internal coupling. L denotes the reactor, x and y the splitting and confluence points, respectively, and MV and SV the main and secondary valves, respectively.

When using a single injection valve, the most immediate use is the insertion of a preset liquid volume of sample into a carrier or reagent stream that is also a liquid. In the reverse FI mode, abundance of sample acts as a carrier where the reagent is injected. Also, there are possible FI configurations into which gaseous samples are inserted into liquid or vice versa. The insertion of this volume into a stream can be either time based or volume based (the latter being the most frequently used). Despite these general functions of the devices, other multiple functions of volume-based injection systems demonstrate their versatility. These functions are performed with the help of some devices working in a continuous fashion and located in the valve loop. These devices, inserted into the dynamic system, range from microcolumns packed with different materials to detector cells, and also include other continuous separation units such as dialyzers, gas-liquid separators, liquid-liquid extraction cells, filters, and pervaporation chambers.

The easy manipulation and arrangement capacity of single injection valves enable their coupling in different manners. In-parallel coupling enables sample-sample injection and sample-reagent injection facilitating the symmetrical or asymmetrical modes of the merging-zone approach. In-series coupling of these valves allows zone sampling and a variety of manifolds for simultaneous determinations. Finally, the interior coupling, the so-called nested loop approach, has demonstrated high versatility. Multi-determinations, calibration and speciation studies, construction of pH gradients, and blank-sample measurements are the more remarkable applications of this configuration.

Solenoid valves and commutators are among the volume-based injection systems less commonly used in FI. The latter have been used by their inventors – a Brazilian team – but they are not practical devices as they easily deteriorate.

### Transport-Reaction Systems

In addition to its primary function of carrying the flowing stream along the manifold and allowing, where appropriate, a reaction to develop to a suitable extent, the transport and reaction system serves to link the different parts of the FI system. This component normally consists of small-bore tubes of internal diameter between 0.1 and 1.0 mm, but usually 0.3, 0.5, and 0.7 mm internal diameters for low, medium, and high dispersion requirements, respectively. Large bores are of little use as the remaining FI components are not designed to match them – tubing expansion and compression of the other components result in irregularities that

significantly affect the dispersion. On the other hand, bores smaller than 0.3 mm internal diameter are only used in the miniaturized FI mode. The reactor, a major component of the transport system, influences the residence time and profile of the sample plug, and is designed to meet the particular requirements of the system concerned. Three basic types of open reactors are used in FI (**Figure 5**): (1) straight tubes of variable length of diameter; (2) coiled tubes, which are pieces of tubing coiled helically around a rigid cylinder of the desired diameter; and (3) knotted tubes, which are much more effective than coiled or straight tubes as far as reduction of dispersion is concerned. However, producing knotted tubes requires skill, and the tubing must be flexible enough and have walls thick enough to prevent collapse or narrowing at tight bends.

The connectors used in FI setups serve the purpose of joining the tubes to one another and to the other parts of the system. There is a wide range of connectors available for each type of application, but basically they are either dual (linear or V-shaped), triple (T-, Y-, or W-shaped), or quadruple (usually in the shape of an arrowhead). The distance between the ends of the two tubes brought together by the linear dual connector should be as small as possible in order to minimize the dead volume, since this acts as a small mini-mixing chamber that results in increased peak tailing. Triple and quadruple connectors are commonly employed for both merging and splitting more than two streams (**D** in **Figure 5**). They make very useful devices for the development of reaction rate methods as the injected plug is split into several subplugs that reach the detector at different times.

The most suitable material for making reactor tubes is polytetrafluoroethylene (PTFE), which, in addition to being chemically resistant, absorbs less solutes on its surface. Polyethylene or polypropylene is inexpensive and easy to flange. As these three materials are highly permeable to oxygen, they pose serious problems in dealing with strong reductants or

**Figure 5** Types of simple open reactors: (A) straight, (B) coiled, (C) knotted, and (D) with splitting and confluence points.

air-catalyzed reactions. Connectors are normally PTFE or polymethylmethacrylate (PMMA).

## Other Units

One of the most interesting features of FI is its great versatility, i.e., the ease with which the manifold lends itself with alteration depending on the type of analyte, sample, or particular requirements involved. Alterations can involve one of the basic units described in the previous section or inclusion of units other than the basic ones, such as special valves, separation modules, packed reactors, or units required for the partial or full automation of the manifold.

## Special Valves

Two special types of valves are often used in FI: (1) special injection valves different from those described above, which allow special FI modes to be implemented; and (2) selecting or switching valves, which enable the streams traveling through the transport–reaction system to be handled as required.

A single eight-port injection valve can perform the same functions as two six-port valves as it can accommodate two loops. This type of valve is commonly used in gradient and sandwich techniques, where the sample is sandwiched between the carrier and a solution containing a reagent or a standard, and then returned to the carrier.

The heart of the sequential injection mode is a multiposition selection valve that is operated in synchronization with a pump. This valve can be connected to various sample and reagent reservoirs and when the pump is operated in reverse, aliquots are sequentially drawn into a holding coil, and, upon forward propulsion, the resultant stack of sample and reagents is dispersed into a zone of detectable product.

Switching valves provide great flexibility in the transport–reaction zones of FI configurations. Thus, the use of one such valve (A in Figure 6) allows selection of different reagents or reaction media for the sequential determination of as many analytes as desired, provided the reagents used are selective enough. A selection valve, placed at the point of splitting of two channels that are merged prior to the detector, allows the sample plug to be driven through one or the other channel, each of which normally includes a different reaction (B in Figure 6).

Open–closed systems are probably the most useful applications of switching valves. The valve keeps the system open in one of its positions, operating as a normal FI configuration (see C in Figure 6). Once the

**Figure 6** Reactors involving additional components such as valves for (A) selection of different reagents, (B) selection of different channels, and (C) closing and opening the circuit. PS denotes the propulsion system, IS the injection system, R the reagent, D the detector, and W the waste.

injected plug is inside, the valve is switched and the system is closed. The plug is then circulated through the manifold, which includes an ordinary detector and an auxiliary propulsion system, and is passed many times through the detection point, thereby yielding a multipeak recording from which large amount of information of theoretical and practical interests can be drawn. Some applications of these systems include determination of reaction orders and rate constants, stoichiometries, multicomponents, etc.

Mixing chambers are used when a high degree of mixing (merging point or unstirred chamber) or complete homogenization of sample and reagent (well-stirred sample) is required, which is usually the case when using an electrochemical detector or when the carrier and sample are considerably different in viscosity, relative density, temperature, or detergent content. Mixing chambers are commonly used in FI titrations.

## Separation Modules

Separation steps are quite often included in the analytical process in order to increase the selectivity and sensitivity of the overall determinations by removing undesirable interferents and preconcentrating the analyte(s), respectively. By appropriately coupling the separation technique and an FI manifold, separation/preconcentration processes can be performed automatically. The major separation techniques that are coupled online with FI manifolds are discussed, and the basic units required in each case are described.

**Figure 7** Continuous separation modules: (A) gas diffuser or dialyzer and (B) liquid-liquid extractor with extraction of the analyte(s) into the organic phase.

Figure 7A shows the scheme of a typical gas diffuser for use in FI, whether a chemical reaction is needed from the gas (e.g., carbon dioxide, ammonia, sulfur dioxide, or hydrogen sulfide) or the gas occurs as such in the sample (e.g., nitrogen oxides,  $\text{ClO}_2$ , ethanol, or ozone). The unit comprises a sandwich cell consisting of two blocks (PMMA or PTFE) with identical internally engraved conduits that make up an inner chamber, the geometry and dimensions of which vary from model to model. A membrane (usually Teflon) is placed between the two blocks, which must be joined tightly in order to avoid leakage. Each microconduit has two holes at its ends that connect it with the manifold tubing. The dimensions of the conduits engraved in the blocks vary over the following ranges: 0.1–0.3 mm depth, 1–3 mm width, and 3–10 cm length. Tubular cells including PTFE tubes and membranes are less commonly used for this purpose. The separation efficiency of the gas-diffusion process can be improved by including a derivatizing reaction in the acceptor stream in order to effect continuous removal of the analytes from the vicinity of the membrane, thereby also creating a useful concentration gradient.

In a dialysis process, separation of the different solutes relies on the difference between the rates at which they are transferred across a semipermeable membrane located between the two liquid phases and across which mass transfer takes place. The type of the membrane is the key difference between gas-diffusion and dialysis units; both use identical modules. Dialyzers are normally placed in the transport-reaction zone, and they are also occasionally positioned in the loop of the injection valve for

increasing dialysis efficiency. In such instances, the acceptor stream remains static or is recirculated, as required. Dialyzers accommodated in flow cells are not intended to effect the separation proper, but to facilitate the introduction of a reagent in order to accomplish integrated reaction and detection. On the other hand, placing a dialyzer at a point in the sample channel prior to the injection valve is quite common in online process monitoring, particularly in biotechnological applications to avoid contamination of fermentation tanks by microorganisms. For this purpose, laboratory-built or commercially available modules are furnished with sterilizable membranes.

A continuous liquid-liquid extractor receives separate streams of two immiscible phases and establishes a segmented flow within. Ordinary liquid-liquid extractors consist of three basic elements that are connected online (Figure 7B) in the following sequence: a solvent segmenter, an extraction coil, and a phase separator. The solvent segmenter – a minimixing chamber or a merging point – receives the streams of the two immiscible phases and establishes an outgoing flow consisting of alternate, regular segments of the two phases, which is driven to the extraction coil. The phase separator is the most important element of a liquid-liquid extractor in relation to smooth functioning. It receives the segmented liquid-liquid flow from the extraction coil and separates the segments in such a way that two independent streams of the two phases emerge from it. The separation of the immiscible phases can be based on density differences or the selective wetting of a special membrane by one of the phases – normally the organic phase. The operation of all three elements relies on two fundamental principles: (1) the density difference between the immiscible phases and (2) the selective wetting of the inner component surfaces by both organic and aqueous phases. As a rule, organic solvents wet PTFE and other plastic surfaces, whereas aqueous phases wet glass surfaces; conversely, organic solvents are repelled by glass surfaces and aqueous phases are rejected by PTFE surfaces. Indeed, complete phase separation is accomplished rarely and only when special requirements are met. Thus, the actual purpose of this element is to provide a flow of one of the two phases containing none of the other. The phase in question is usually the one containing the analyte or its reaction product, and also includes one that is subsequently driven to a continuous detector.

The extractor can be located at two different points in the FI manifold:

1. Before the injection valve in the sample stream, which is usually the aqueous phase. The

outgoing organic phase containing the analyte(s) fills the loop of an injection valve through which a carrier continuously passing through the detector is circulated. In the inject position, the organic content of the valve loop is directly transferred to the detector.

2. After the injection valve, where the sample is injected into an aqueous carrier that can continuously merge with one or several reagent streams. This and another stream carrying an organic solvent converge in the extractor. Finally, the outgoing phase stream is monitored in a continuous fashion.

Some atypical FI liquid–liquid extraction systems do not use any proper separation unit, but an emulsion, an organized medium, a minicolumn capable of retaining one of the phases involved in the extraction process, or a reversed-flow system. A number of ingenious approaches for FI liquid–liquid extraction without phase separation have been designed.

### Packed Reactors

The use of solid-phase reactors coupled online to FI manifolds significantly increases the potential of FI by enhancing such basic analytical parameters as sensitivity and selectivity and allowing implementation of specific reactions. These reactors involve (bio)chemical reactions – whether enzymatic, immunoassay, ion exchange, or redox – or act as sorbent extractants or reagent releasers.

The minicolumn – tubular or conical in shape – is usually made of glass, PTFE, Tygon<sup>®</sup>, or PVC, and is 10–50 mm long and has an internal diameter of 1.5–3.0 mm. The location of these reactor(s) in an FI manifold depends on the type of material with which they are packed, which in turn is determined by their function in the overall process. **Figure 8** shows the different possible locations of these units:

1. Before the injection system, whether in the carrier or in the sample stream, for removal of reagent

**Figure 8** Possible locations for a minicolumn containing a solid reagent in an FI manifold.

impurities and release of reagents, or for matrix interference removal or preconcentration purposes, respectively.

2. In the loop of the injection valve, for preconcentration, multianalyte determinations, or simultaneous blank and sample measurements.

3. Between the injection and detection units, the most common location for a solid reactor in an FI manifold. The aim in this case can be any of those described above.

4. In the detection system, the main aim being integration of the reaction (retention) and detection in order to exploit some of the typical advantages of these approaches: enhanced sensitivity, selectivity, sampling rate, miniaturization, etc.

In addition to the use of immobilized enzymes on suitable supports, which results in decreased costs in routine analyses, the solid forms of these biocatalysts provide a number of additional advantages, the most immediate of which are: (1) simplification of the FI manifold required (use of an additional channel with a point of merging with the sample stream or an additional valve for simultaneous sample–enzyme injection is thus avoided) and (2) increased sensitivity as a result of the lower dilution of the sample on mixing with the enzyme solution. This latter advantage is even more apparent when several enzymatic steps involving different biocatalysts are required to obtain a measurable product. A serial arrangement of as many reactors as steps to be developed is very useful for this purpose. Immuno-reactors with either membranes or magnetic particles as the solid phase for the bound antibodies can also be used.

Ion exchange or sorption microcolumns coupled in-line in an FI manifold are used for two main purposes: preconcentration of the analyte(s) and removal of interferences using a support suited to the species to be retained. The two most serious shortcomings arising from the use of this type of microreactor are: (1) the increased compactness of the packed material resulting from continuous circulation of the flow in the same direction and (2) the appearance of parasitic signals at the detector as the sample matrix passes through the detection point during the preconcentration process. Both shortcomings are overcome by introducing a very simple change in the FI system, i.e., by placing the reactor in the loop of an injection valve in order to perform retention in the direction opposite to elution.

Redox reactions are used in FI systems for two main purposes: (1) to convert the analyte to an appropriate oxidation state for development of the subsequent derivatization reaction, thus avoiding

dilution arising from the merging with a redox solution and (2) for in-line formation *in statu nascendi* of strong reductants, thus making possible the use of redox agents in unstable oxidation states.

The most commonly used material for packing adsorptive reactors included in FI manifolds is C<sub>18</sub>-bonded silica beads and, to a lesser extent, alumina and silica. Preconcentration is by far the most common function of these reactors (especially of metal ions prior to their determination by atomic absorption or emission spectrometry). Enrichment factors of up to 50 are readily obtained with the aid of conical reactors, the direction of which in the manifolds is arranged in such a way that the adsorbed analytes are eluted from the wider to the narrower end of the column in order to minimize dispersion in the column.

Reagent-releaser reactors make very useful means of increasing sensitivity through substantially decreased dilution. In addition, they simplify the FI manifold as merging points and auxiliary channels are made redundant. These reagents are packed in cartridges or bound to resins.

## Detectors

Most of the detectors coupled to FI manifolds have been conventional instruments (e.g., molecular, atomic optical, or electrochemical) capable of providing only two-dimensional information. In this case, a simple flow cell or direct aspiration to the atomizer is the only interface required. In a parallel but delayed development of hyphenated systems in chromatography, the coupling of FI with high discrimination instruments pointed out the maturity of this technique. This step in FI started with the FI-ICP-AES coupling. More recent and less numerous have been the arrangements of FI with instruments that enable three-dimensional information and high discrimination capabilities, like mass spectrometry – by direct coupling or through an inductively coupled source – Fourier-transform infrared and nuclear magnetic spectroscopies, among the most important. The design of the interface for these couplings clearly limits the performance of the overall system.

## Automation of a Flow Injection Analyzer

Strictly speaking, FI is not an automatic or automated technique as only the transport and detection systems work continuously in any FI manifold. Indeed, for any of these systems to be categorized

as automatic or automated, the injection operation itself must be performed automatically. In addition, automation of the go-stop sequence of the propulsion unit is mandatory in order to implement stopped-flow methods, while automation of the data acquisition system is required when fast detectors are used, and that of switching valves is required in open-closed systems and other types of manifolds using them.

The old-fashioned components needed for full automation of an FI analyzer include electrical step motors for mechanically actuating valves and controlling the go-stop sequence of the propulsion system. Presently, RS-232 interfaces are used to allow for computer control and frame programs make operation very easy by including the corresponding steps of a given process in the general frame. The inclusion of triggers enables decisions to be taken by the analyzer, which thus becomes automated.

Automated sample introduction requires a sampler in addition to automated functioning of the injection valve when the analyzer is not devoted to online monitoring. These samplers are of the same type as those used for air-segmented systems and flame atomic absorption spectrometers. The liquid samples are transferred into individual vessels that are placed either on a circular turntable or in a square-shaped rack. The sampling time is preset so that the injection loop is completely filled. The washing or rinsing time – i.e., the time during which the sample probe either resides in a wash or rinse bath or is aspirating air – is also predetermined. The cycle time is the sum of the sampling time and the washing or rinsing time. The most commonly used samplers for FI work through the samples position by position on the turntable – random access samples are not normally used in FI analyzers. Carryover is usually a minor problem for most sampler types. A washing solution can be aspirated in between aspiration of different samples. Aspiration of air during the wash cycle is often quite sufficient. If the sample volume is a matter of concern when multiple analyses are to be performed, then the pump aspirating the sample should be programmed to be halted over the analysis time.

### Introduction

Flow injection analysis (FIA) is a popular methodology with widespread use largely because it can employ any detection system that is capable of accepting a flowing stream. In many instances, the flow pattern of a liquid stream passing through a particular detector is not disrupted, so that additional detection systems can be arranged in series for multiparametric measurements in a single sample zone injected. In recent years, daughter flow techniques such as sequential injection analysis (SIA), multi-commuted flow injection analysis, and multisyringe flow injection analysis have emerged as competitive methodologies of the former, especially in terms of versatility and online coupling to different detection instruments for sequential monitoring of key analytes. Moreover, the discontinuous operation of these novel techniques has expanded the applicability of flow systems, so that discrete, non-flow-through detection principles can also be hyphenated.

In general, detectors can be classified according to the way in which the analyte or reaction product is probed, i.e., whether it is done by bulk or surface sensing. It is also possible to draw a distinction between flow-through detectors measuring an intrinsic property of the analyte and those requiring prior online derivatization. From the point of view of instrumental requirements, it is more appropriate to

make the classification according to the underlying detection principle as presented in this article.

An ideal detector integrated in a flow manifold should possess several attributes, which in many respects are identical to those demanded for liquid chromatography. Accordingly, fast response, small dead volumes, wide dynamic ranges, high sensitivity, low noise level, reproducible and stable response, independence of the signal with fluctuations in flow velocity, simplicity of design, miniaturized size, robustness, and moderate cost are desirable. No existing detector fulfils the entire set of aforementioned requirements, and therefore a compromise between the various factors should be considered.

This article provides some general remarks on detection requirements for FIA and related techniques and outlines the basic features of the most commonly used detection principles, including optical methods (namely, ultraviolet (UV)–visible spectrophotometry, spectrofluorimetry, chemiluminescence (CL), infrared (IR) spectroscopy, and atomic absorption/emission spectrometry) and electrochemical techniques such as potentiometry, amperometry, voltammetry, and stripping analysis methods. Very few flowing stream applications involve other detection techniques. In this respect, measurement of physical properties such as the refractive index, surface tension, and optical rotation, as well as the  $\alpha$ -,  $\beta$ -, or  $\gamma$ -emission of radionuclides, should be underlined. Piezoelectric quartz crystal detectors, thermal lens spectroscopy, photoacoustic spectroscopy, surface-enhanced Raman spectroscopy, and conductometric detection have also been coupled to flow systems, with notable advantages in terms of automation, precision, and sampling rate in comparison with the manual counterparts.

## Introduction

Flow injection analysis (FIA) is a popular methodology with widespread use largely because it can employ any detection system that is capable of accepting a flowing stream. In many instances, the flow pattern of a liquid stream passing through a particular detector is not disrupted, so that additional detection systems can be arranged in series for multiparametric measurements in a single sample zone injected. In recent years, daughter flow techniques such as sequential injection analysis (SIA), multi-commuted flow injection analysis, and multisyringe flow injection analysis have emerged as competitive methodologies of the former, especially in terms of versatility and online coupling to different detection instruments for sequential monitoring of key analytes. Moreover, the discontinuous operation of these novel techniques has expanded the applicability of flow systems, so that discrete, non-flow-through detection principles can also be hyphenated.

In general, detectors can be classified according to the way in which the analyte or reaction product is probed, i.e., whether it is done by bulk or surface sensing. It is also possible to draw a distinction between flow-through detectors measuring an intrinsic property of the analyte and those requiring prior online derivatization. From the point of view of instrumental requirements, it is more appropriate to

make the classification according to the underlying detection principle as presented in this article.

An ideal detector integrated in a flow manifold should possess several attributes, which in many respects are identical to those demanded for liquid chromatography. Accordingly, fast response, small dead volumes, wide dynamic ranges, high sensitivity, low noise level, reproducible and stable response, independence of the signal with fluctuations in flow velocity, simplicity of design, miniaturized size, robustness, and moderate cost are desirable. No existing detector fulfils the entire set of aforementioned requirements, and therefore a compromise between the various factors should be considered.

This article provides some general remarks on detection requirements for FIA and related techniques and outlines the basic features of the most commonly used detection principles, including optical methods (namely, ultraviolet (UV)–visible spectrophotometry, spectrofluorimetry, chemiluminescence (CL), infrared (IR) spectroscopy, and atomic absorption/emission spectrometry) and electrochemical techniques such as potentiometry, amperometry, voltammetry, and stripping analysis methods. Very few flowing stream applications involve other detection techniques. In this respect, measurement of physical properties such as the refractive index, surface tension, and optical rotation, as well as the  $\alpha$ -,  $\beta$ -, or  $\gamma$ -emission of radio-nuclides, should be underlined. Piezoelectric quartz crystal detectors, thermal lens spectroscopy, photoacoustic spectroscopy, surface-enhanced Raman spectroscopy, and conductometric detection have also been coupled to flow systems, with notable advantages in terms of automation, precision, and sampling rate in comparison with the manual counterparts.

Special emphasis is given in the bulk of the text to the design criteria for both flow-through cells and

bio(chemical)sensors and also to the particular and unique benefits that arise from the hyphenation of flow systems with detection techniques.

## Optical Detection

### UV-Visible Spectrophotometry

Through all the 30 years of development of flow injection analysis, photometry has been, and currently is, the detection technique most commonly interfaced with flow systems. Traditionally, common batchwise-operating spectrophotometers have been adapted easily to the flow requirements. Different commercially available U-, Z-, or oval-shaped flow-through cells (typically of 10 mm path length) are in widespread use (see Figure 1A–1C). Additional efforts have been focused recently on improvement of the sensitivity of the UV-visible spectrophotometric methods through the design of novel cells with optical paths longer than 20 mm. Although different materials have been assessed, all long path length cells suffer severe interference problems due to light attenuation and scattering. The novel synthesized cladding material Teflon AF-2400 warranted the use of liquid-core waveguide (LCW) flow cells (depicted in Figure 2A) with lengths as high as 200 cm. Since the refractive index of this polymeric material is lower than that of water, total reflection of light can be achieved by careful selection of the incident angle on the water/Teflon interface. The particular feature of this material with respect to fused silica, employed as a total reflection surface in organic media, is its unique behavior as a gas-diffusion membrane, which enables detection of volatile species.

A typical problem encountered in flow injection photometry is the influence of the Schlieren effect due to changes in the refractive index between the different zones delivered to the detector. The

appearance of artifact signals over the transient profile deteriorates the sensitivity and repeatability of the measurements. This effect has been minimized using capillary flow cells wherein the light beam is directed to the optical detector perpendicular to the flow direction (see **Figure 1D**). Dual-wavelength detection is a commonly exploited alternative to compensating instrumentally the spectral shift caused by refractive index gradients. In recent years, this aim was accomplished using optical fiber-based micro-computer plug-in or charge coupled device spectrophotometers, which in combination with solid-state light emitting diodes (also available as multidiode light sources) enabled the design of portable and miniaturized detectors. The hyphenation of FIA with downsized photometers has been shown to be well suited for in-field environmental monitoring without the need for discrete sample collection and storage. A further advantage of fast scanning array spectrophotometers is the capability to exploit multidetermination through instantaneous full spectral acquisition and chemometric data processing. Simultaneous discrimination of various species in a single sample plug based on the reaction rate differences is also attained using laboratory-made serial or combined flow cells.

In the context of automation of the microfluidic handling of solutions and microminiaturization, the novel concept of lab-on-valve (LOV) in combination with SIA is worth mentioning. It is based on integrating a set of microconduits within a multipurpose valve, which allows a plethora of unit operations to be implemented. Optical detection in the microflow analyzer is performed easily via optical fibers assembled to the flow conduits. The sensitivity of the photometric measurements can be adjusted to the requirements of the assay through reconfiguration of the integrated system, so that different path lengths are available as shown schematically in **Figure 2B**.

In recent years, different flow cell designs have been proposed aiming to prevent the entrapment of bubbles of out-gassed air within the light path junctions, which disturbs the signal profile and worsens the signal-to-noise ratio. In this respect, the construction of multireflection flow cells consisting of a straight tube (made for example from Teflon AF-2400) that is illuminated from one side should be pointed out. In case gas bubbles enter, they are not retained and exit with the same velocity as the flowing solutions. An elegant strategy for overcoming the adherence of bubbles to the flow walls consists of exploiting a liquid drop as an optical cell. The windowless nature of the drop-based cell with a single collector fiber also enhances the capabilities of flow injection systems to accommodate turbidimetric/nephelometric detection

since the elimination of the windows overcomes the shortcoming of deposition of precipitate into the flow-through cell.

### Luminescence Detection

Despite the limited number of species that exhibit luminescent properties, fluorescence and (electro)chemiluminescence detection have been used extensively as detection techniques in flowing stream systems. This is a consequence of the much wider range of response, better selectivity, and lower detection limits achieved in comparison with molecular absorption spectroscopic methods. The outstanding benefits of flow injection systems for fluorescence measurements are the controlled chemical conditions that can be created in a highly repeatable manner and the fact that oxygen quenching may be readily minimized in the closed environment provided by the automated technique. Moreover, commercially available spectrofluorimeters furnished with flow-through quartz cells can be used without additional modifications. In recent years, spectrofluorimetry in combination with FIA/SIA can be regarded as a powerful hyphenated tool for performing multiparametric detection exploiting variable angle scanning fluorescence. The feasibility of implementing the stopped-flow mode required for recording the total luminescence data matrix and also pH gradient techniques for improving both the quantification limits and the spectral discrimination of the set of analytes is specially worth mentioning. The unique optical property of Teflon AF previously mentioned permitted the construction of a simple, portable, and stable transversely illuminated LCW laser-based fluorescence detector.

The analytical application of CL detection has been given a strong impetus by the advent of flow systems. The reproducible mixing of streams and precise timing control inherent to FIA are indispensable conditions for reliable CL measurements. Flow injection should be highlighted as a unique strategy for accommodating fast CL reactions, very often involving catalyzed-luminol oxidation, wherein light emission occurs instantaneously upon merging the sample and chemiluminogenic reagent with half-life times of only a few seconds. The coupling of enzymatic heterogeneous reactions using packed-bed or open-tubular reactors with CL detection has been presented as a useful online approach for indirect determination of several organic substrates. Immobilization procedures warrant low consumption of the expensive catalysts and enhanced enzyme stability. Yet, handling of soluble enzymes using multi-commutation protocols or merging-zones in FIA is

demanding for those preparations whose active groups are susceptible to being blocked during immobilization. It should also be stressed that the novel multisyringe flow injection principle, which includes the noteworthy features of FIA and SIA schemes, has been proved to be an excellent alternative to performing automated CL assays with different kinetic requirements without requiring manifold reconfiguration.

Instrumentally, CL measurements are extremely simple since no wavelength-restricting devices are necessary. The detector consists of a suitable flow-through cell, typically a spiral-shaped cell, placed in front of the window of a photomultiplier tube (PMT) as shown in **Figure 3A** and **3B**. In recent years, new designs with a larger surface, such as the fountain cell illustrated in **Figure 3C**, have been explored for CL detection. This cell geometry enables suitable collection of emitted light as a consequence of the accommodation of the entire sample volume within the observation area. High sensitivity is also attained with LCW-based detectors because of the effective transfer of the CL emission. Recording of the overall intensity–time profile is ensured with sandwich-type units furnished with a reading optical fiber since the analyte and reagents are mixed where the detection takes place. With respect to luminol electrochemiluminescence, novel configurations relying upon the working electrode facing the PMT have been devised during recent years. FIA has also been shown to be suitable for gas-phase CL involving the reaction of

nitric oxide in dried air (generated from nitrate, nitrite, or ammonium) with ozone supplied by an ozone generator.

### IR Spectroscopy

IR spectroscopy is a direct probe of molecular vibrations so that with few exceptions, practically all molecular species exhibit a unique IR absorption spectrum. In spite of this fact, the applicability of this detection technique for quantitative measurements in flowing stream systems has been rather limited in comparison with UV–visible and luminescence detection. This is a consequence of the greater complexity of the spectra, the overlapping of bands between moieties of different compounds, and the limitations of IR instruments. The potential of this technique has been enhanced via application of multiplex systems based on the Fourier transform (FT) algorithm. Fast spectra scanning and high resolution measurements are warranted exploiting FT-IR (FTIR) spectroscopy. Due to the powerful spectral information supplied by FTIR spectroscopy and the fact that the Lambert–Beer law is obeyed, many flow injection applications are devoted to the simultaneous determination of active constituents or pesticides in complex mixtures using multivariate data analysis (mainly partial least squares regression models). A plethora of flow methodologies use the information-rich mid-IR spectra in combination with organic carriers with a large absorption-free area such as chloroform. Flow-through

R, reagent; S, sample; C, carrier; PMT, photomultiplier tube.

cells with sodium chloride or potassium bromide windows assembled in a liquid nitrogen-cooled mercury–cadmium–telluride detector have been employed commonly.

The applicability of mid-FTIR spectroscopy to aqueous solutions typically handled in flow manifolds is restricted to the spectral window of the range of  $1400\text{--}1000\text{ cm}^{-1}$  owing to the strong absorption of water. In this region, novel pH-modulation approaches for organic acids based on the laminar flow of aqueous streams (viz., alkaline sample and acidic solutions) through a sheath-flow cell configuration have been developed. The analytical readout is taken from the spectral changes induced by the pH change of the sample.

In case of measurements in the zone of the bending vibration of water, which also corresponds to the information-rich amide-I band of proteins, optical paths below  $10\text{ }\mu\text{m}$  are required to prevent large interference effects. Such short path lengths are available using either dedicated transmission cells or attenuated total reflection (ATR) approaches. However, both strategies have poor sensitivity as a result of the short optical path and also present practical problems for repeatable measurements. To circumvent these shortcomings, new IR light sources of high intensity, such as quantum cascade lasers, which enable transmission measurements at extended path lengths, have been adapted to FIA/SIA.

It should also be emphasized that the coupling of FIA/SIA with diamond-based ATR probes for online bioprocess monitoring was found to be an excellent alternative to *in situ* measurements aiming to overcome biofilm formation and gas bubble adherence to the surface of the ATR element.

### Atomic Spectrometry

Although originally FIA was conceived as a special technique for delivery of a sample segment into the instrument, the combination of flow injection as a sample pretreatment tool with atomic spectrometry has been shown to be of great potential for enhancing the selectivity and sensitivity of the measurements. Moreover, contamination problems are reduced due to the closed system used, making this interface suitable for ultratrace determination of metal species. Hyphenated techniques such as FIA/SIA with flame atomic absorption spectrometry, inductively coupled plasma (ICP)–optical emission spectrometry, and ICP–mass spectrometry (MS) have been exploited extensively in recent years. The major attraction of FIA–ICP–MS is its exceptional multi-elemental sensitivity combined with high speed of analysis. In addition, the possibility of

performing isotope and isotope-ratio analysis offers unique applications. The capabilities of FIA–ICP–time-of-flight–MS as a fast transient detector for simultaneous determination of a large number of isotopes in a FIA peak have also been evaluated thoroughly.

Flow rates of FIA systems for sample introduction are usually compatible with the continuous working mode of the aforementioned techniques and permit online operation using relatively straightforward interfaces. The interfacing of FIA with ICP–MS, for example, is attained readily by connecting the outlet of the FIA manifold with the liquid flow inlet of the detector nebulizer through a short length of narrow-bore tubing. It has also been reported that an improvement in nebulization efficiency and a facile adjustment of the signal magnitude may be accomplished via optimized automatic methods. Besides, sample injection into a continuously pumped carrier solution at a constant flow rate (instead of the conventional aspiration) minimizes transport interferences due to differences in viscosity of the samples and eliminates carry-over effects between consecutive samples owing to the periodical rinsing of the nebulizer. The ability to handle sample volumes at the microliter level also prevents some interfering processes, such as matrix deposition in the nebulizer. Hyphenated techniques allow a multitude of different injection modalities to be assessed. In this respect, merging-zones approaches, microsampling systems, and hydrodynamic injections have been proposed for decreasing sample and/or reagent consumption with regard to manual procedures. Monosegmented sample injection using air-segmentation was proved to be effective in restricting axial dispersion and in improving sampling throughput. It should also be highlighted that atomic spectrometry is the field where the largest amount of research effort on developing new FIA calibration methods has been focused. In this context, methodologies relying upon reproducible formation of the concentration gradient (namely, gradient dilution or gradient ratio methods) as well as clever designs for automatic standard additions calibration using merging-zones, zone penetration, gradient dilution, or interpolative strategies are particularly worth mentioning.

The practical applicability of absorption and emission spectrometric techniques is frequently restricted by spectral and nonspectral interferences due to their inherently low tolerance limit to sample constituents present in complex matrices. The most adequate way of alleviating the interfering effects consists of performing appropriate online sample pretreatment prior to analysis using flowing stream schemes. In many

instances, matrix separation is accompanied concurrently with analyte preconcentration. Hence, different FIA/SIA-hyphenated techniques involving co-precipitation with metal chelates, solvent extraction/stripping approaches, sorption on polytetrafluoroethylene knotted reactors, and microcolumn solid-phase extraction in a renewable fashion via the bead-injection (BI)-LOV principle have proven very effective.

The entire set of separation/preconcentration methodologies is equally applicable to electrothermal-atomic absorption spectrometry (ETAAS). It should be emphasized that the discontinuous operation of the SIA technique is better suited than FIA systems for hyphenation with ETAAS as a consequence of the discrete, non-flow-through nature of the detector. Moreover, the replacement of peristaltic pumps with syringe pumps as liquid drivers enables handling of minute, well-defined volumes with higher precision. Thus, the extremely low sample/eluent volumes able to be accommodated in the graphite tube ( $< 50 \mu\text{l}$ ) are manipulated easily with the automated SIA assembly and injected generally into the furnace via air-segmentation.

Vapor generation (VG) techniques involving hydride formation and cold vapor methods for monitoring metalloid species and mercury, respectively, have profited greatly from FIA in terms of a more than 90% reduction in sample and reagent consumption, two- to threefold higher sampling frequencies, better coefficients of variation, and significantly enhanced tolerance to interferences due to kinetic discrimination. Many efforts have recently been made to design novel gas-liquid separators for improved gas-phase separation. In the case of metalloid determination, FIA has been presented as a powerful tool for implementing speciation protocols through careful control of the experimental variables, such as the tetrahydroborate concentration for the formation of the volatile species; the selective complexation of trivalent or pentavalent species; the sequential volatilization of hydride species following cryogenic trapping; or the operational control of focused microwaves. *In situ* trapping of hydride species onto a Pd- or Ir-coated graphite tube of an ETAAS detector and mercury enrichment as a gold amalgam prior to detection enabled lowering the detection limits by more than order of magnitude. Very recently, the coupling of FIA-VG with atomic fluorescence spectrometry has been presented as a promising alternative to atomic absorption methods. The equipment is simpler and less expensive, and improved tolerance to organic compounds along with better determination limits is obtained usually.

## Electrochemical Detection

The hydrodynamically well-defined conditions of flow systems are an ideal environment for electrochemical detectors, resulting in enhanced performance characteristics. The surface sensing properties of most electrochemical methods require particular attention in the construction of suitable flow-through cells. Efficient and repeatable mass transport toward the electrode surface is necessary, and dead volumes should be small. Various flow-through cells have been designed for electrochemical detection, all of which can be derived from the basic configurations depicted in Figure 4.

Electrochemical methods are subjected markedly to the interfering effects caused by adsorption of high molecular weight organic species on the electrode surfaces. Yet, matrix interferences can be alleviated considerably with the beneficial features resulting from interfacing FIA with membrane separation processes. As an alternative, online matrix removal with concomitant analyte preconcentration prior to the measurement of the electrical property may be performed via sorbent extraction procedures.

### Potentiometry with Ion-Selective Electrodes

Potentiometry is the most common method of electrochemical detection used in flow injection analysis. This methodology creates more favorable conditions for potentiometric measurements when compared to batch procedures. In FIA measurements, it is easier to avoid incidental contamination or that resulting from leakage of the solution from the reference electrode. Moreover, deactivation of the sensing surface of the indicator electrode due to adsorption, precipitation, or corrosion is minimized greatly as a consequence of the short contact time with the sample

**Figure 4** Basic configuration of flow-through cells applied in electrochemical flow methods. The position of the working/indicator electrode is marked by gray areas.

plug. An additional advantage resulting from the continuous flow of the sample zone is the improved selectivity attained exploiting the mechanism of kinetic discrimination between the analyte and the interfering species. The response time limitation of potentiometric detectors under dynamic regime for low analyte concentrations, which is observed mainly as a slow return of the potential value to the baseline level, can be overcome readily in FIA by addition of a small concentration of the sensed ion to the carrier stream. Flow systems are also useful schemes for proper sample presentation to the selective sensor since common strategies such as buffering, ionic-strength adjustment, pH control, and addition of masking agents are easily performed.

Another outstanding feature of using potentiometric detection in combination with FIA is the relative ease of construction of flow cells for implementing conventional electrodes or dedicated flow-through detectors. Careful consideration of the position of the indicator and reference electrode is essential to avoid artifact transient signals due to the influence of junction and streaming potentials. The most common types of flow-through cells used in FIA systems with commercially available ion-selective electrodes (ISEs) or photocured coated wire ISEs involve cascade designs, thin-layer cells, or wall-jet configurations (see **Figure 4** for further details). Although the latter arrangement provides the best dynamic performance and smaller carry-over effects, thin-layer cells are specially adapted to accommodating an array of sensing electrodes for multidetermination. In some instances, combination of the signals of the electrodes via multiplexed readings aiming to produce a more intense signal and an improvement in the precision of individual measurements has been explored.

Amongst dedicated potentiometric detectors, tubular cells with solid-state crystalline homogeneous membranes or with polyvinyl chloride or epoxy resin layers containing appropriate ionophores have been implemented successfully in flow manifolds. This configuration circumvents the problems that the incorporation of conventional-shaped units in FIA assemblies have in terms of mechanical stability. It should be stressed that difficulties in fixing the electrode in a rigid way can lead to an increase in noise and dead volumes, affecting the repeatability and return to the baseline. Further advantages include the maintenance of the sample dispersion profile and the avoidance of air bubble entrapment. Enhancement of the sensitivity of potentiometric tubular detectors in FIA has been achieved using double-membrane systems coupled with external electronic summing devices or dual detector systems in series wherein

one of the electrodes works alternatively as a reference electrode.

Progress in analytical potentiometry in recent years has brought a miniaturization of detection systems via the hyphenation of the sensor with a large extent of integration electronics. In this context, chemically sensitive layers are placed directly onto field effect transistors (FETs) to produce ion-selective FETs (ISFETs). The use of two identical ISFETs in a flow-through cell offers the possibility of differential measurements without the influence of the liquid junction potential.

### Amperometric and Voltammetric Detection

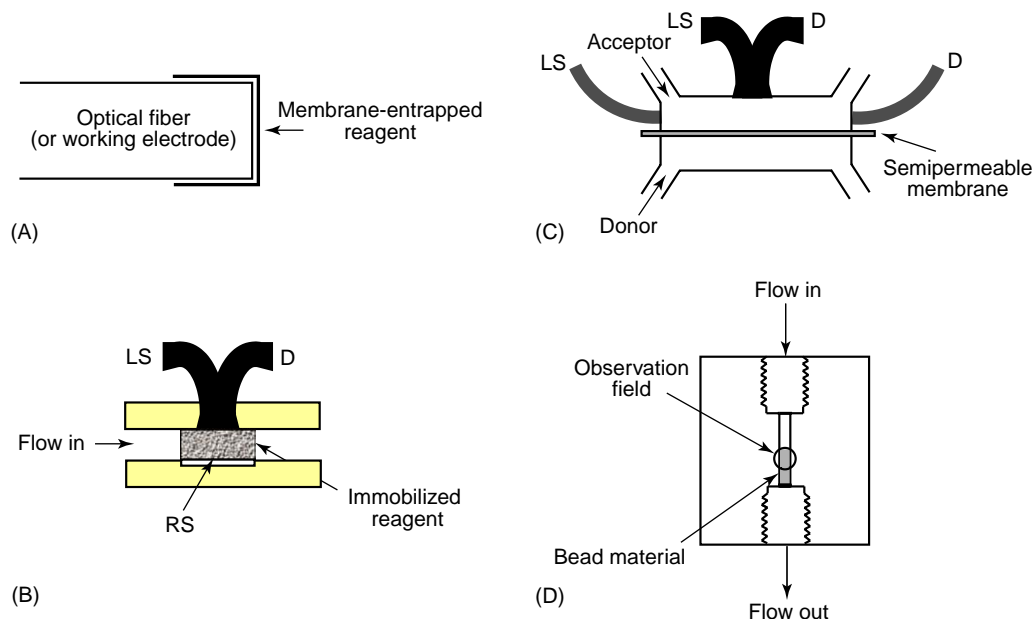

Despite the limited selectivity achievable with amperometric and voltammetric detection, their application in FIA has attracted the attention of many researchers. Flow systems provide suitable schemes for isolation of the analyte prior to detection and also the capability to implement selective biocatalytic reactions. The majority of developed flow injection amperometric procedures are performed in a three-electrode configuration, with constant polarization of the working electrode. Although glassy carbon is the material par excellence employed, modification of the electrode surface with species of electrocatalytic behavior is frequently demanded for minimizing overpotential effects. Selectivity improvement for electrochemical measurements is usually carried out by suitable conditioning of the electrode or by implementation of a polymeric layer exhibiting selective permeability or electrocatalytic properties. Furthermore, a marked increase in sensitivity can be achieved by exploiting pulse polarization techniques that enhance the faradaic current of the electroactive species. With regard to the flow cells used in flow injection amperometry, wall-jet and thin-layer arrangements should be highlighted. Different configurations are reported in the literature aiming to minimize the ohmic drop by proper positioning of the set of electrodes. It should be stated that the wall-jet design can be used not only with solid disk working electrodes but also with the hanging mercury drop electrode (HMDE). Very recently, an ultra-simple adaptor for converting batch cells with the HMDE in detectors for flow injection amperometric analysis, compatible with all the different brands and operating modes of the HMDE, has been described. A crucial parameter to take into account in these electrochemical techniques is the severe dependence of the flow rate on the current measurements, and thus a periodical recalibration of the liquid driver is required to prevent drastic oscillations of the hydrodynamic parameters.

The advantage of voltammetric methods, wherein current is measured as a function of the varying polarization of the working electrode, is the likelihood of performing multicomponent detection. Yet, a careful choice of the sweep rates in FIA is needed to avoid large background signals due to the changing current. In order to obtain the desired resolution of the voltammetric peaks, a fast scan rate with differential pulse or square-wave voltammetry has been used. When overlapping of several voltammetric signals is detected, data processing using a Kalman filter is known to be effective for deconvolution of the overall signal.

Metal traces are commonly determined in electrochemical procedures by flow injection anodic stripping voltammetry. Preconcentration of the desired species with the subsequent isolation from the matrix constituents is generally performed using mercury film electrodes. Stripping of the reduced species through an appropriate potential scan allows simultaneous determination of various metal ions. The basic advantages of performing stripping measurements in a dynamic mode are the ability to change the reaction medium conditions, which may be needed for the different stages of the stripping procedure, and the easy contamination control via the automation of the analyses.

## (Bio)chemical Sensors

In recent years, there has been increasing interest in the design of extrinsic optical fiber chemical (bio)sensors (i.e., (bio)optrodes) relying upon monitoring the optical properties of a reagent phase attached at the end of the optical fiber (as detailed in Figure 5A) that change on exposure to the analyte or an active derivative. They combine the advantages of optical fibers with the specificity and selectivity of the sensing element. Similarly, the immobilization of an enzyme or a component of an immunochemical assay at the surface of an electrochemical or piezoelectric detector, and also within the electrode material, allows the design of new detection devices for analytical purposes, so-called biosensors. Although these bio(sensors) have been traditionally used as probes for batch measurements, their implementation in flowing stream systems has opened new perspectives in the field of optical/electrochemical sensing owing to the ability to automate both the sample conditioning and sensor regeneration steps as well as to the ready miniaturization, facile handling, and individual optimization of the unit operations involved. It should be mentioned that though ISEs are a generic kind of chemical sensor, their fundamentals and application in flowing stream systems have been included in a separate section.

**Figure 5** Schematic illustrations of several bio(sensor) configurations assembled in flowing stream systems. (A) Probe-type configuration based on the modification of the optical fiber or working electrode with a reagent/catalyst containing membrane; (B) sandwich-type cell for optical-fiber-based reflectance measurements on a pad or thin layer with immobilized reagent; (C) membrane-based flow through sensor for absorbance or reflectance measurements in the receiver stream; (D) dedicated sorbent-packed planar-wall flow-through cell designed for solid-phase absorptiometry. LS, light source; D, detector; RS, reflecting surface.

The incorporation of the active microzone within the flow manifold has launched the development of flow-through (bio)sensors based on integrated (bio)chemical reaction and detection. Since the first application to reflectance measurements for pH monitoring using the scheme depicted in Figure 5B, optosensing techniques in flow injection systems have been exploited using very different sensing surfaces, such as thin membranes, cellulose pads or strips, or glass/polymeric beads accommodating indicators, chromogenic ligands, ionophores, or catalysts. In order to achieve the sensitivity requirements for many assays, optosensing preconcentration strategies have been adopted by several researchers. In the case of volatile analytes, a suitable means of increasing the enrichment factors consists of using flow-through gas-diffusion optosensors (see Figure 5C) in an acceptor stopped-flow alternative.

A common approach to integrating separation, preconcentration, and detection in flow-through sensors relies upon solid-phase optical detection onto sorbent bead materials packed in commercially available flow-cells. Yet, novel dedicated configurations with different path lengths involving tubular microcolumns, prismatic-shaped cells (shown in Figure 5D), and sandwich-type arrangements (especially useful for disk-based extraction procedures) have been evaluated for spectrophotometric and reflectance measurements. The pursued aim is minimizing the background attenuation, collecting the maximum amount of scattered light, and diminishing the optical dilution of the analyte retained. The noteworthy features of the on-column detection principle with regard to liquid-phase readings are the elimination of the artifact signals resulting from the Schlieren effect and the prevention of dispersion of the preconcentrated analyte, which is the most severe pitfall of sorbent extraction/elution microcolumn-based flow systems with eluate sensing.

The novel concept of BI commonly associated with sequential injection systems represents a remarkable progress in the field of flow-through solid-phase (bio)optosensors. It has also been introduced as a powerful tool for automation of immunoassays in both the jet-ring cell and lab-on-valve configurations. As a consequence of its renewable nature, BI presents several advantages for proper sensor performance with respect to optosensing strategies with permanent packed-bed reactors. Amongst them, the suitability for implementing irreversible reagent-based assays as well as the long-term operational applicability due to the absence of both sorbent compaction

(or clogging) and alteration of sorption behavior as a result of surface deactivation should be highlighted.

### Introduction

Flow techniques are being consolidated as powerful tools for the routine control of parameters in various samples of environmental and agricultural origin. The outstanding features of flow injection analysis (FIA) for analytical applications are its extremely straightforward configuration, easy operation, and low costs. Automated analyses with high sample throughput are attained using relatively simple instrumentation. The microformat of FIA results in considerable reduction of sample and reagent consumption compared to classical wet-chemical methods of analysis. Furthermore, as opposed to air-segmented flow analysis (SFA) methodologies, the reproducible timing and readily controllable dispersion of the analyte zone allows the performance of kinetic measurements without demanding steady-state conditions. Other differential features of FIA in relation to SFA are the injection of smaller sample volumes (of the order of 10–100  $\mu\text{l}$ ), the suppression of the washing cycles, the increase of the sampling throughput up to 120 injections  $\text{h}^{-1}$ , the repeatability improvement, and especially the ease of manifold construction and flexibility. The ready adaptation of batch methods permits FIA to be used in compliance with many official standard methods (namely, US Environmental Protection Agency (EPA), International Standards Organization, and European Norms; see comments in Table 1). Environmental safety is another attribute of FIA. The closed-system chemistry not only decreases contamination of the sample but also prevents technicians coming into contact with hazardous chemicals. Moreover, as a consequence of its inherent miniaturization, a considerable decrease in waste generation, and hence also in costs for waste disposal, is achieved. FIA has also attracted the attention of many researchers owing to its ability to fulfill the current demands in environmental analysis. The fast response of FIA makes the analytical information available in real time, which is especially desirable in monitoring schemes, some of the flow analysers being included in EPA directives. FIA has

also been exploited for in-field analysis aiming to obtain high temporal and spatial resolution data without the need for discrete sample collection and storage. This is of great interest whenever offline analysis or excessive sample handling is unacceptable due to the rapid transformation of the target analyte.

Despite the aforementioned benefits of FIA with regard to manual procedures and precedent flow techniques, the incompatibility of the elastic tubes of peristaltic pumps with concentrated acid or bases and organic solvents usually forces the periodical recalibration of the system or the incorporation of more expensive reagent-resistant tubing. The physical adsorption of organic analytes onto the Tygon tubes is another practical limitation commonly described. Though performance of multiparametric determinations using a single multidetection system or several detectors arranged in series has been reported in several studies, the simultaneous monitoring of various environmental parameters have been rather limited to particular applications. It should be also stressed that the continuous flowing of solutions according to FIA philosophy results in the consumption of carrier, reagent, and sample during the overall analysis protocol.

Sequential injection analysis (SIA) was proposed in 1990 as a new concept for handling solutions alternatively to FIA. Whereas in conventional FIA manifold the sample volume is inserted into the carrier stream and subsequently merged downstream with reagents, SIA methodology is based on the software-controlled sequential aspiration of precise volumes of sample and reagent, which are afterwards dispensed into the reaction coil by flow reversal. Therefore, a considerable sample and reagent saving is achieved – of the order of 20 times in relation to FIA. The replacement of the FIA injection valve with a rotary selection valve has enabled the incorporation of additional reactors/modules, the performance of backward–forward flow movements, the exploitation of stopped-flow schemes, and the simple development of multiparametric determinations by coupling different detectors and appropriate reagents to the multiposition valve. The use of syringe pumps as liquid drivers has allowed the manipulation of sample and reagent volumes at the low microliter level with high precision. The microanalytical features of SIA, along with the handling of the exact volumes required for the particular assays, have opened new avenues in the monitoring of environmental parameters. For example, atmospheric

**Table 1** Analytical features of flowing-stream methods applied to the determination of relevant parameters in natural, tap, wastewaters, and industrial effluents

Analyte	Method/reagents/ derivatization reaction	Detection	Working range	Particular features
Ammonium	Berthelot	Spectrophotometry	0.010–1.0 mg N l <sup>-1</sup>	Replacement of phenol by salicylate
	Nessler	Spectrophotometry	0.050–0.50 mg N l <sup>-1</sup>	Coating of the colloidal product on the tubing walls
	GD – boric acid, HCl, or distilled water as acceptors	Conductimetry	0.010–0.50 mg N l <sup>-1</sup>	Conductivity changes
	GD – pH indicator	Spectrophotometry	0.010–1.0 mg N l <sup>-1</sup>	Standard method EN/ISO 11732
	ISE containing the nonactin ionophore	Potentiometry	0.8–140 mg N l <sup>-1</sup>	Gas-diffusion/use of activated carbon to remove interfering organic compounds
	Ion-selective coated wire electrode	Potentiometry	0.14–1400 mg N l <sup>-1</sup>	Portable battery-powered analyzer
	Clinoptilolite-modified electrode	Amperometry	0.28–14 mg N l <sup>-1</sup>	Copper-doped electrode
	NaClO-luminol	Chemiluminescence	0.05–0.4 mg N l <sup>-1</sup>	Indirect measurement
	Hypochlorite-ozone	Chemiluminescence	0.0014–1.4 mg N l <sup>-1</sup>	Gas-phase detection
	OPA	Spectrofluorimetry	0.0004–0.7 mg N l <sup>-1</sup>	Use of nucleophilic species
Nitrite	Griess-Ilosvay	Spectrophotometry	0.010–0.70 mg N l <sup>-1</sup>	Simultaneous determination of nitrate using a Cu–Cd column/standard method EN/ISO 13395
	Griess-Ilosvay/reversed-phase extraction	SPS	0.3–30 µg N l <sup>-1</sup>	Solid-phase optrode
	Gallocyanine	Spectrophotometry	0.003–0.80 mg N l <sup>-1</sup>	Catalytic reaction
	Naphthol Green B	Spectrophotometry	0.6–60 µg N l <sup>-1</sup>	Catalytic reaction
	3-Aminonaphthalene-1,5-disulfonic acid	Spectrofluorimetry	> 14 µg N l <sup>-1</sup>	Formation of an azoic acid salt
	3,3',4,4'-Biphenyltetramine	Spectrofluorimetry	9–30 µg N l <sup>-1</sup>	Direct determination
	Rhodamine 6G/bromate	Spectrofluorimetry	2.4–30 µg N l <sup>-1</sup>	Kinetic method
	Iodide	Biamperometry	0.02–14 mg N l <sup>-1</sup>	Detection of the tri-iodide generated
	Carbon paste electrode modified with a ruthenium polymer	Amperometry	0.0007–7 mg N l <sup>-1</sup>	Decrease of the overpotential for nitrite oxidation
	Griess/Cu–Cd	Spectrophotometry	0.060–11.30 mg N l <sup>-1</sup>	Online reduction to nitrite
Nitrate	No reagent	Spectrophotometry	0.10–3.10 mg N l <sup>-1</sup>	Direct UV detection-multivariate analysis
	Griess/photo-induced reduction	Spectrophotometry	> 0.42 µg N l <sup>-1</sup>	Use of EDTA as activator
	Luminol/UV irradiation	Chemiluminescence	0.001–1.4 mg N l <sup>-1</sup>	Generation of peroxynitrite species
	Tubular ISE composed of a DPNi containing film	Potentiometry	> 3.4 mg N l <sup>-1</sup>	Assessment of various ionic strength modifiers
	Sodium peroxodisulfate/hydrazine/Griess	Spectrophotometry	0.20–20 mg N l <sup>-1</sup>	Online microwave-assisted digestion
Total nitrogen	Alkaline peroxodisulfate/Cd-column/Griess	Spectrophotometry	0.03–3.0 mg N l <sup>-1</sup>	Online photo-oxidation
	Sodium peroxodisulfate/Cu–Cd column/Griess	Spectrophotometry	> 5.0 µg N l <sup>-1</sup>	Thermal digestion using a capillary tube containing a Pt wire
Orthophosphate	Molybdenum blue	Spectrophotometry	0.010–0.25 mg P l <sup>-1</sup>	Use of antimony as a catalyst
	Molybdenum blue	Spectrophotometry	> 0.2 µg P l <sup>-1</sup>	Solid-phase extraction
	Molybdate/vanadate	Spectrophotometry	0.15–18 mg P l <sup>-1</sup>	Detection of the yellow complex without reduction
	Molybdate/malachite green	Spectrophotometry	0.010–0.10 mg P l <sup>-1</sup>	Ion-pair association

Table 1 Continued

Analyte	Method/reagents/ derivatization reaction	Detection	Working range	Particular features
Phosphorus species	Molybdate/rhodamine B	Spectrofluorimetry	0.0003–0.095 mg P I <sup>-1</sup>	Quenching of fluorescence
	Molybdate/thiamine	Spectrofluorimetry	0.007–6.6 mg P I <sup>-1</sup>	Generation of fluorescent thiochrome
	Pyruvate oxidase G/luminol	Chemiluminescence	0.003–1.0 mg P I <sup>-1</sup>	Generation of hydrogen peroxide via enzymatic reactions
	Glassy carbon electrode	Amperometry	0.006–0.32 mg P I <sup>-1</sup>	Free of silicate interference
	Cobalt wire electrode	Potentiometry	3.1–310 mg P I <sup>-1</sup>	Indirect determination
	Sodium peroxodisulfate in acidic medium/molybdate/ascorbic acid	Spectrophotometry	0.010–1.0 mg P I <sup>-1</sup>	Determination of dissolved organic phosphorus/online UV-photo-oxidation/standard method EN/ISO 15681
Silicate	Thermal (or microwave-assisted) digestion in acidic medium/molybdate/tin(II) chloride	Spectrophotometry	0.020–2.0 mg P I <sup>-1</sup>	Determination of total dissolved phosphorus previous acidic hydrolysis of condensed phosphates
	Molybdenum blue	Spectrophotometry/ICP-AES	0.1–200 mg P I <sup>-1</sup>	Serial arrangement of detectors for the determination of orthophosphate and total phosphorus
	Molybdenum blue	Spectrophotometry	0.14–1.4 mg Si I <sup>-1</sup>	Addition of masking agents (tartaric or oxalic acids)/standard method EN/ISO 16264
	Molybdate/rhodamine B	Spectrophotometry	0.17–2.0 mg Si I <sup>-1</sup>	Ion-pair association
Sulfate	Molybdate	Spectrophotometry	3.5–80 mg Si I <sup>-1</sup>	Simultaneous determination of orthophosphate and silicate exploiting the differences of reaction rates
	Molybdate	Spectrophotometry	0.8–15 mg P I <sup>-1</sup>	
	Molybdate	Spectrophotometry	0.9–30 mg Si I <sup>-1</sup>	Selection of appropriate acidity and sample segmentation with oxalic acid
	Molybdenum blue	Spectrophotometry	0.2–12 mg P I <sup>-1</sup>	
	Molybdenum blue	Spectrophotometry	5.0–50 mg Si I <sup>-1</sup>	Selection of appropriate concentration of oxalic acid
	Molybdenum blue	Spectrophotometry	0.2–7.0 mg P I <sup>-1</sup>	
	Barium chloride in a polyvinyl alcohol medium	Turbidimetry	5.0–200 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Addition of alkaline EDTA to avoid the build-up of precipitate
	Barium dimethylsulfonazo-III	Spectrophotometry	0.2–14 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Color-fading reaction
Sulfide	Ferric nitrate	Spectrophotometry	10–1000 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Sample pretreatment with activated charcoal is required to remove interfering organic species
	Methylthymol blue (MTB)	Spectrophotometry	0.025–1.0 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Solid-phase extraction/detection of the MTB–Ba complex
	Barium chloranilate	Spectrophotometry	4.0–100 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Displacement reaction
	BANH-Zr	Spectrofluorimetry	1.5–150 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Comparison of various manifolds
	MTB-Zr	Spectrophotometry	0.5–20 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Catalytic reaction
Sulfide	Lead nitrate	Potentiometry	100–1000 mg SO <sub>4</sub> <sup>2-</sup> I <sup>-1</sup>	Use of a Pb-ISE
	Nitroprusside	Spectrophotometry	0.5–10 mg S <sup>2-</sup> I <sup>-1</sup>	No concentrated aggressive reagents are required

Table 1 Continued

Analyte	Method/reagents/ derivatization reaction	Detection	Working range	Particular features
Chloride	Methylene blue	Spectrophotometry	$0.01\text{--}15\text{ mg S}^{2-}\text{ l}^{-1}$	30-fold sensitivity increase with regard to nitroprusside method
	Methylene blue and nitroprusside	Spectrophotometry	$>0.2\text{ }\mu\text{g S}^{2-}\text{ l}^{-1}$	Gas-diffusion separation/preconcentration using a halted recipient solution
	Direct determination on a glassy carbon electrode	Amperometry	$0.03\text{--}24\text{ mg S}^{2-}\text{ l}^{-1}$	Adaptable to on-board measurements
	Sulfide-sensitive electrode	Potentiometry	$1\text{--}1000\text{ mg S}^{2-}\text{ l}^{-1}$	Tubular electrodes with homogeneous crystalline membranes or treated silver foils
	2,6-Dichlorophenol-indophenol modified electrode	Amperometry	$0.65\text{--}32\text{ mg S}^{2-}\text{ l}^{-1}$	Long-term stability
	Mercury(II)thiocyanate/Fe(III)	Spectrophotometry	$1.0\text{--}1000\text{ mg Cl}^{-}\text{ l}^{-1}$	Standard method EN/ISO 15682
	Hg-EDTA	Spectrophotometry	$>0.2\text{ mg Cl}^{-}\text{ l}^{-1}$	UV detection
	Mercury(II)thiocyanate	Spectrophotometry	$0.16\text{--}2000\text{ mg Cl}^{-}\text{ l}^{-1}$	Absence of Fe(III)
	Ag (or Hg)-chloranilate	Spectrophotometry	$1.0\text{--}20\text{ mg Cl}^{-}\text{ l}^{-1}$	Use of a solid reagent reactor
	AgNO <sub>3</sub>	Turbidimetry	$3.0\text{--}30\text{ mg Cl}^{-}\text{ l}^{-1}$	Recirculation of reagent in a closed system
Residual chlorine	Chloride-ISE	Potentiometry	$0.1\text{--}10\,000\text{ mg Cl}^{-}\text{ l}^{-1}$	Wide dynamic range/standard method EN/ISO 15682
	Dedicated Ag-ISE	Potentiometry	$2.0\text{--}90\text{ g Cl}^{-}\text{ l}^{-1}$	Online titration
	Methyl orange	Spectrophotometry	$0.1\text{--}10\text{ mg Cl}^{-}\text{ l}^{-1}$	Color fading reaction
	4-Nitrophenylhydrazine	Spectrophotometry	$0.05\text{--}40\text{ mg Cl}^{-}\text{ l}^{-1}$	Generation of azo-dye species (or measurement of decrease of reagent absorbance)
	<i>o</i> -Tolidine	Spectrophotometry	$0.5\text{--}5.0\text{ mg Cl}^{-}\text{ l}^{-1}$	Formation of an unstable hydroquinone
	<i>o</i> -Dianisidine	Spectrophotometry	$0.05\text{--}1.30\text{ mg Cl}^{-}\text{ l}^{-1}$	Gas-diffusion/tandem-flow approach
	Gold electrode	Amperometry	$>7.0\text{ }\mu\text{g Cl}^{-}\text{ l}^{-1}$	Useful for monochloramine determination
	Rhodamine 6G	Chemiluminescence	$0.07\text{--}7.0\text{ mg Cl}^{-}\text{ l}^{-1}$	Electrostatic immobilisation of the reagent
	Disproportionation of chlorine into HClO and Cl <sup>-</sup>	Potentiometry	$0.7\text{--}7.0\text{ mg Cl}^{-}\text{ l}^{-1}$	Gas-diffusion separation/Cl-ISE
	<i>N,N</i> -diethyl- <i>p</i> -phenylenediamine/KI	Spectrophotometry	$0.1\text{--}8.0\text{ mg Cl}^{-}\text{ l}^{-1}$	Sequential determination of free and combined chlorine
Fluoride	KI/UV detection	Spectrophotometry	$0.03\text{--}3.0\text{ mg Cl}^{-}\text{ l}^{-1}$	Determination of total chlorine
	Fluoride-ISE	Potentiometry	$0.005\text{--}50\text{ mg F l}^{-1}$	High selectivity, wide dynamic ranges, and low detection limits
	Lanthanum(III)/alizarin complexone	Spectrophotometry	$0.03\text{--}3.5\text{ mg F l}^{-1}$	Sensitivity improvement via addition of cationic surfactants
	Zr(IV)-SPADNS	Spectrophotometry	$0.02\text{--}3.5\text{ mg F l}^{-1}$	Inhibitory effect
Bromide	Lanthanum(III)/alizarin complexone	ICP-AES	$0.03\text{--}1.3\text{ mg F l}^{-1}$	Liquid-liquid extraction/indirect determination
	Phenol red	Spectrophotometry	$0.16\text{--}2.4\text{ mg Br l}^{-1}$	Formation of the bromophenol blue dye

Table 1 Continued

Analyte	Method/reagents/ derivatization reaction	Detection	Working range	Particular features
Iodide	Tetrapase/chloramine T	Spectrophotometry	1.0–40 $\mu\text{g Br I}^{-1}$	Catalytic reaction
	Permanganate/Pt-electrode	Amperometry	> 0.08 mg Br I <sup>-1</sup>	Gas-diffusion
	Iron(III) thiocyanate	Spectrophotometry	0.75–150 $\mu\text{g I I}^{-1}$	Fading effect
	Dichromate/KI (receiver)	Spectrophotometry	> 0.2 mg I I <sup>-1</sup>	Gas-diffusion
	Ce(IV)/As(III)	Spectrophotometry	0.002–0.5 mg I I <sup>-1</sup>	Sandell–Kolthoff's reaction
	Sodium nitrite	MIP-AES	> 2.3 $\mu\text{g I I}^{-1}$	Generation of volatile iodine
Bromate	Cr(VI)	FAAS	6.0–220 $\mu\text{g I I}^{-1}$	Indirect method/sorption of formed Cr(III) onto a chelating column
	Chlorpromazine	Spectrophotometry	1.0–30.0 $\mu\text{g BrO}_3^- \text{ I}^{-1}$	Masking strategies are required to minimize interference from nitrite and chlorite
Chlorate/chlorite	Ion-exchanger/ammonium hydroxide	ICP-MS	0.06–50 $\mu\text{g BrO}_3^- \text{ I}^{-1}$	Selective elution of bromide and bromate from an activated alumina microcolumn
	KI/HCl	Spectrophotometry	0.1–10.1 mg ClO <sub>2</sub> <sup>-</sup> I <sup>-1</sup> 0.1–8.3 mg ClO <sub>3</sub> <sup>-</sup> I <sup>-1</sup>	Speciation is possible due to the different acidic requirements for iodide oxidation
Cyanide	Chloramine-T/pyridine-barbituric acid	Spectrophotometry/ Amperometry	0.002–2.0 mg CN <sup>-</sup> I <sup>-1</sup>	Gas-diffusion preconcentration/UV-photolysis for total cyanide determination/ standard method ISO 14403
Surfactants	Metallic silver-wire electrode	Potentiometry	0.05–250 mg CN <sup>-</sup> I <sup>-1</sup>	Gas-diffusion/use of a non-selective sensor
	Luminol/Cu	Chemiluminescence	0.005–2.0 mg CN <sup>-</sup> I <sup>-1</sup>	Luminol oxidation by Cu(CN) <sub>4</sub> <sup>2-</sup>
	Hypochlorite/rhodamine B	Chemiluminescence	0–50 mg I <sup>-1</sup>	Determination of amine ethoxylate-based nonionic surfactant
	Alizarin fluorine blue	Spectrophotometry	0.2–12.0 mg I <sup>-1</sup>	Determination of Triton-type surfactants
	Bromocresol purple	Spectrophotometry	> 10 <sup>-6</sup> mol I <sup>-1</sup>	Determination of cationic surfactants
	Luminol/ <i>N</i> -bromosuccinimide (or <i>N</i> -chlorosuccinimide)	Chemiluminescence	10 <sup>-6</sup> –10 <sup>-4</sup> mol I <sup>-1</sup> (CPC, DTAB, CTAB)	Decrease of chemiluminescence emission at surfactant concentrations below the critical micelle concentration
DIC	Methylene blue (standard method EN/ISO 16265) or rhodamine B	Spectrophotometry (or spectrofluorometry)	> 0.03 mg I <sup>-1</sup> (C <sub>12</sub> -alkylbenzene sulfonate)	Solvent extraction/on-tube detection
	GD-Cresol Red or 4-(2',4'-dinitrophenylazo)-1-naphthol	Spectrophotometry	10 <sup>-6</sup> –10 <sup>-3</sup> mol I <sup>-1</sup>	Color change of acid–base indicators
	GD-NaOH (acceptor stream)	Conductimetry	> 3 × 10 <sup>-6</sup> mol I <sup>-1</sup>	Measurement of signal decrease
	GD-H <sub>2</sub> SO <sub>4</sub> (donor stream)	QCM	5 × 10 <sup>-4</sup> to 2 × 10 <sup>-2</sup> mol I <sup>-1</sup>	Transient variation of the monitored frequency of QCM on CO <sub>2</sub> passage
TOC	GD-HNO <sub>3</sub> (donor stream)/N <sub>2</sub> (recipient stream)	FTIR	> 7.5 × 10 <sup>-5</sup> mol I <sup>-1</sup>	Gas-phase detection
	GD-carbon dioxide detection	Spectrophotometry/ infrared spectrometry	10 <sup>-6</sup> –10 <sup>-4</sup> mol I <sup>-1</sup>	Photochemical oxidation

precipitates are often only present in limited quantities or long collection times are required, so that microsampling is extremely beneficial. The main drawback of SIA for analytical applications is the lower sampling rate achieved in relation to FIA as a consequence of the periodical filling of the liquid driver and the stacking of the entire set of segments in the holding coil. Besides, the sequential and non-simultaneous propelling of the solutions that takes place in SIA results in longer residence times for proper interdispersion between zones. This shortcoming has been already solved by replacing the multiposition SIA valve with solenoid valves or miniaturized integrated conduits, so that novel flow techniques such as the so-called multicommutated flow injection analysis, multisyringe flow injection analysis (MSFIA), and sequential-injection lab-on-valve have been recently designed. These methodologies, which include the outstanding features of the parent FIA and SIA schemes, have proven effective tools for the miniaturization and automation of

environmental assays and also for performing reliable sample pretreatments. **Figure 1** illustrates various flowing-stream configurations devised for the spectrophotometric or spectrofluorimetric monitoring of several analytical parameters in aqueous samples.

In this article, flowing-stream systems assembled for environmental and agricultural analysis are classified according to their application area, i.e., water, air, soil, and plant analysis. Within each area relevant flow methodologies for the determination of individual analytes are briefly reviewed and specific features of particular methods are outlined. Additional information about the analytical performance of several flow assemblies is listed comprehensively in the tables. The likelihood of direct introduction and treatment of solid samples in an automated fashion is also highlighted in the bulk of the text. Finally, attention is also paid to the different schemes available for online speciation studies, which are of increasing significance in environmental assays.

**Figure 1** Schematic illustration of flowing stream manifolds devised for the automatic determination of relevant environmental parameters in water samples using various flow techniques: (A) flow injection analysis, (B) sequential injection analysis, (C) multicommutation flow injection analysis, (D) multisyringe flow injection analysis. The sequential injection-lab-on-valve configuration is depicted in previous article: Flow injection analysis-detection techniques. S, sample; R, reagent; C, carrier; D, detector; IV, injection valve; HC, holding coil; RC, reaction coil; MV, multiposition valve; SV, solenoid valve; SP, syringe pump; MP, multisyringe pump; PP, peristaltic pump; St, stopper; W, waste.

## Determination of Nutrients, Anionic Species, and Related Compounds in Waters

Flow techniques are particularly suitable for monitoring environmental parameters in waters. Moreover, flow methods offer unique possibilities for automatic sample pretreatment, involving inline dilution or filtration, adjustment of viscosity, ionic strength, or pH as well as removal of solid and colloidal matrix constituents via in-line dialysis separation techniques.

Most of water matrices (viz. drinking, marine, salty, river, waste, ground, estuarine, cooling, and thermal power plant water) may be easily handled with flow systems. Since the analytical methods performed to date are likely suitable for the determination of the specific parameter in different kinds of matrices, the applications of flow systems will be reviewed according to the target analyte – following the practical guidelines for water-quality surveillance, instead of attending the sample source. The analytical features of relevant flowing-stream methods applied to environmental water analysis are comprehensively compiled in Table 1.

## Nitrogen Compounds

**Ammonium** The determination of ammonium is of significant interest in pollution control and environmental evaluation of water. Current flow injection spectrophotometric strategies are based upon the Berthelot reaction since it is highly selective for ammonium, its repeatability is excellent, and in the presence of catalysts, such as sodium nitroprusside, low detection limits are attained. The Nessler reaction has also been implemented in flow systems, yet its applicability was limited by the precipitation of the colloidal product onto the inner walls of the poly(tetrafluoroethylene) (PTFE) tubing. One of the most promising methodologies for the selective determination of ammonium involves the implementation of gas-diffusion units in flow injection devices coupled mainly to spectrophotometric detection, notwithstanding conductometric and potentiometric detections have also been proposed. In the latter case, the membrane-based ammonium ion-selective electrode (ISE) containing the nonactin ionophore has been widely used. Nevertheless, photo-cured membranes on silver wires are recommended owing to the excellent adhesion to the metal substrate and improved mechanical strength. With regard to

amperometric detection, ion-doped clinoptilolite or polyaniline-modified electrodes have been successfully assembled in flow injection devices. Sensitive chemiluminescence (CL) methods include the measurement of light emission decrease from NaClO–luminol system or the gas-phase monitoring of the reaction product between ozone and nitric oxide resulting from analyte oxidation. Luminescence methods relying on derivatization reactions with o-phthalaldehyde in the presence of nucleophilic species have been reported as convenient procedures for ammonium determination in a variety of water matrices.

**Nitrite** Nitrite is an important indicator of fecal pollution in natural waters as well as a potential precursor of carcinogenic species. A rush of flow and sequential injection spectrophotometric method based on Griess-type reactions has been proposed, also coupled to online sorbent enrichment schemes. The catalytic effect of nitrite on the oxidation of various organic species constitutes the basis of fairly sensitive spectrophotometric methods. Fluorometric methods based on the formation of aromatic azoic acid salts, quenching of Rhodamine 6G fluorescence, and direct reaction with substituted tetramine or naphthalene species have been also reported. Indirect CL methods usually involve conversion into nitric oxide and gas-phase detection as mentioned in the foregoing section. The redox reaction between nitrite and iodide in acidic media is the fundamental of a plethora of flow injection methodologies with spectrophotometric, CL, or biamperometric detection. New electrochemical sensors with chemically modified carbon paste electrodes containing ruthenium sites, or platinum electrodes with cellulose or naphthalene films, have recently attracted special attention for amperometric detection.

**Nitrate and total nitrogen** One of the primary steps for environmental studies concerning water quality, sanitation, and public health is the determination of nitrate. Runoff from fields treated with fertilizers is the major cause of nitrate pollution of river and underground waters. High levels of nitrate are toxic to children. Flow and sequential injection spectrophotometric procedures for nitrate as well as total oxidized nitrogen determination are almost entirely based on the heterogeneous online reduction to nitrite using a copperized cadmium reactor. Yet, the homogeneous reduction of the analyte by hydrazine or ultraviolet (UV) irradiation has also been investigated by several authors. Photochemical activation is also well suited for CL detection, since peroxo-nitrite species, which are the oxidizing agents for

luminol, are formed during the process. Highly sensitive enzymatic methods based on the spectrophotometric monitoring of the nicotinamide adenine dinucleotide phosphate reduced by the nitrate reductase enzyme have been presented. Potentiometric detection using tubular-shaped electrodes or heterogeneous membrane-based ISEs is also commonly exploited in flowing systems.

Suitable alternatives to the batch digestion methods for total nitrogen determination include online UV photodegradation in the presence of oxidizing agents and online microwave-assisted chemical digestion with alkaline peroxodisulfate. The resulting inorganic nitrogen species are determined using the methods described above.

### Phosphorus and Silicon Compounds

Determination of orthophosphate is of great importance in water-quality surveillance since this compound is regarded as the best indicator of the nutrient status of natural waters. The chemical basis of spectrophotometric flow procedures for monitoring dissolved reactive phosphorus lies in the reduction of the molybdophosphate complex (molybdenum blue method) in the presence of antimony to enhance the reaction yield, although detection of the yellow molybdovanadophosphate complex has also been reported. Spectrophotometric alternatives comprise the formation of ion pairs of heteropoly acid species with cationic complexes or basic dye compounds such as Rhodamine B, Crystal Violet, and Malachite Green. Fluorometric determinations relying upon the generation of the fluorescent thiochrome or on the quenching of fluorescence of various Rhodamine species are frequently performed. Moreover, highly sensitive CL-based biosensors involving enzyme-packed bead reactors have been very recently devised. Several researchers described the electrochemical reduction of the heteropoly acid to molybdenum blue at a glassy carbon electrode without silicate interference. Indirect potentiometric determination of orthophosphate in wastewaters has been proven effective using a Co-ISE. The overall methodologies have also been applied to dissolved organic phosphorus determination following mild inline photo-oxidative decomposition. Yet, monitoring of total dissolved phosphorus requires previous acidic hydrolysis of condensed phosphates.

Silicate is an essential element and even a limiting micronutrient for some aquatic microorganisms. Its concentration drives the growth of a large part of the siliceous phytoplankton. Determination of dissolved silica (viz. orthosilicic acid and its dimer) is generally performed by flow injection spectrophotometric

procedures based on the formation of the yellow  $\beta$ -silicomolybdic acid, its reduction product, or ion-associate complexes. As a consequence of the close chemistry between orthophosphate and silicate, both species severely interfere with the determination of each other. The interference of orthophosphate in silicate monitoring methods is overcome by the addition of tartaric or oxalic acids, which are capable of decomposing selectively the molybdophosphate complex. The concentration of masking agent may be also adjusted to avoid the molybdosilicic acid formation in the determination of orthophosphate. The different rates of formation of both heteropoly acids and the dependence of the color development on the acidity of the reaction medium have also been exploited as discrimination procedures.

### Sulfur Compounds

Though sulfate is one of the major components of natural waters, its determination is of particular interest with respect to the problems of acid rain and water pollution. The widespread industrial use of sulfuric acid makes the monitoring of sulfate decisive for environmental protection. Five spectrophotometric methodologies commonly exploited in the flow or sequential injection fashion are the barium (or lead) sulfate turbidimetric method, the barium dimethylsulfonazo-III approach, the UV-detection of the iron(III) sulfate complex, the methylthymol blue procedure, and the barium chloranilate (or barium chromate) displacement reaction. The major shortcoming of the above methods is their limited selectivity owing to the nonspecific reaction involved. The implementation of online cation-exchange separation processes and the addition of masking agents overcome this drawback. The participation of sulfate in both the formation of fluorophore ternary complexes and the catalysis of the slow reaction between methylthymol blue and zirconium constitutes the basis of fairly sensitive methods. Water quality assessment has been frequently performed using both lead and barium-coated ISEs, although improved detectability is readily attained following in-line solid-phase preconcentration onto anion exchangers.

Sulfide is mainly produced in natural waters from the oxidation of organic matter, and it is highly toxic to most aquatic organisms. Extensive sample manipulation should be avoided in order to minimize loss of analyte by air oxidation or volatilization, and hence flow methodologies are advantageously used. Both methylene blue and nitroprusside methods are the most popular spectrophotometric procedures to measure the sulfide content in various water matrices. Isolation and preconcentration steps for matrix

removal and determination of sulfide at trace levels usually involve sorbent extraction strategies following analyte derivatization or permeation of hydrogen sulfide through porous membranes into a stationary acceptor solution. Electrochemical techniques well adapted to portable flow devices such as amperometry with integrated calibration units or potentiometry using tubular ISEs with homogeneous crystalline membranes, or treated silver foils have been proposed by other researchers. The electrocatalytic oxidation of the target species using an indophenol-modified glassy carbon electrode has been evaluated and successfully applied to the monitoring of sulfide in urban wastewater treatment plants.

### Halogen and Pseudohalide Compounds

One of the most useful chemical analysis to assess the salinity, river and ocean flow patterns, and seawater contamination of estuarine areas, is the determination of the concentration of chloride in environmental waters. The most frequently exploited methodology relies upon chloride reaction with mercury(II) thiocyanate in an iron(III)-containing medium. Spectrophotometric detection in the UV region of either the Hg-ethylenediaminetetraacetic acid-Cl ternary chelate or the  $\text{Hg}(\text{SCN})_2\text{-Cl}$  complex in the absence of iron(III) has also been investigated. Additional indirect photometric methods based on the principle of ion exchange of easily detectable anions versus chloride from suitable mercury salts, such as the UV determination of chloranilate ions, should be mentioned. Aiming to prevent the use of mercury-containing reagents, automated turbidimetric procedures involving silver chloride precipitation have been very recently reported. Amongst the electrochemical methods, the direct or titration-based potentiometric flow systems using dedicated ISEs have attracted the interest of many researchers owing to the wide dynamic ranges and low detection limits attainable as well as the easy adaptation of the electrodes in the flow network.

The inherent toxicity of chlorine and that derived from the production of carcinogenic trihalomethanes has led to the increasing importance of devising robust and simple analyzers for free and combined residual chlorine monitoring. Most of the existing procedures are based upon flow injection spectrophotometric methods comprising color-fading reactions with methyl orange or nitrophenylhydrazine, formation of an unstable hydroquinone with *o*-tolidine, or oxidation of various chromogenic reagents. Amperometric approaches relying on detection of the reduction wave of hypochlorous acid at a gold electrode have been designed and successfully applied to

different kinds of water matrices. The oxidation of organic molecules such as xanthene or rhodamine 6G with free chlorine composes the fundamental of sensitive luminescence procedures. The most widely accepted methodology for measuring total chlorine in waters involves the reaction of chloramines and free chlorine with a potassium iodide stream, and further determination of the iodine generated by UV detection or by reaction with *N,N*-diethyl-*p*-phenylenediamine aiming to form a colored semiquinoid.

Almost all flowing-stream methods reported to date for free and total fluoride determination and applied to quality control and environmental monitoring are related to potentiometric detection using the fluoride ISE owing to its high selectivity. Spectrophotometric alternatives based either on the Alizarin complexone methodology or on the inhibitory effect of fluoride on the formation of different metal chelates have also accomplished a great approval.

Selective determinations of bromide and iodide have been performed by implementation of gas diffusion units for halogen permeation after analyte oxidation with permanganate or dichromate, followed by the phenol red reaction or amperometric measurements, and spectrophotometric detection of triiodide, respectively.

Trace amounts of cyanide are usually determined by flow injection spectrophotometric procedures. The target species is first halogenated with chloramine-T, after which it reacts with a mixture of pyrazolone or barbituric acid and isonicotinic acid or pyridine to form a bluish-violet polymethine dye. The implementation of gas-diffusion modules in the flow setup for hydrogen cyanide separation avoids matrix interferences and enables the adaptation of inherently nonselective detectors, such as metallic silver-wire electrodes for potentiometric measurements. Total inorganic cyanide, including free and complexed species, such as iron-cyanide complexes, may be determined by sample decomposition with UV irradiation and further photometric or amperometric analysis.

### Nonspecific Water Quality Parameters

The presence of pollutants in environmental waters may be detected by the measurement of the chemical oxygen demand (COD). This parameter, which represents the oxygen required for complete oxidation of the organic matter, is, likewise to the batch procedure, evaluated in a flow system as the consumption of a strong chemical oxidant (namely, permanganate, dichromate, or cerium(IV)). The intrinsic drawback of making the COD determination fully automated in flow assemblies owing to the short

residence time of the sample zone as opposed to the conventional procedure may be alleviated by performing online microwave-assisted digestion. Determination of the amount of oxygen taken by microorganisms that decompose organic waste matter, i.e., biochemical oxygen demand, under flow conditions requires the construction of miniaturized microbial sensors based on the combination of an oxygen or optical fiber probe with a culture of microorganisms able to assimilate a wide spectrum of pollutants after immobilization. The measurement of the dissolved inorganic carbon (DIC) after sample pretreatment by wet-chemical oxidation or UV photolysis allows determination of TOC, which is the simplest approach to evaluate the degree of organic pollution without interference of reducing inorganic compounds. DIC is usually monitored using various detection techniques (viz. conductimetry, spectrophotometry, infrared spectrometry, or photoacoustic spectroscopy) following transformation into carbon dioxide, which is trapped in the recipient stream of a gas-diffusion module.

Conductivity measurements are normally performed using purpose-built flow-through cells aimed to avoid flow rate influence. Total ionic concentration is determined by transformation of the salts present in the water sample into their corresponding acids on passing through a cationic exchanger in the proton form, whereupon spectrophotometric titration is carried out. Potentiometric methods for pH measurement using either ionophore-containing photo-cured or poly(vinyl chloride) membrane-based sensors or flat-headed combined electrodes have been readily adapted to automated flow analyzers. To circumvent the classical shortcomings of potentiometric methodologies, several researchers exploited UV-visible spectrophotometric detection with different acid-base indicators. Alkalinity is conventionally measured by online titration with hydrochloric acid as titrant and either methyl orange or methyl red as indicators.

### Metalloid Species and Trace Metals

Metalloid compounds are usually determined by flowing-stream techniques hyphenated with hydride generation (HG)-atomic absorption or atomic fluorescence spectrometry. The continuous operation mode inherent to flow injection is specially suited for the latter detection technique as the tetrahydroborate reagent is a potential source of hydrogen for supporting the flame. Analyte preconcentration is frequently needed to detect the typical levels of metalloid species found in water matrices. In this context, cold trap collection of generated hydrides, sorbent extraction microcolumn methods, sorption

of metalloid derivatives onto the inner walls of PTFE tubes, co-precipitation with lanthanum hydroxide, or retention of volatile compounds onto Pd- or Ir-coated graphite tubes before electrothermal atomization are worth mentioning. Speciation of As and Se has gained increasing importance as the toxic effects of the above species are directly related to their oxidation state. Differentiation between trivalent and pentavalent arsenic is made possible by careful control of the chemical variables, namely tetrahydroborate concentration and pH for arsine generation. Speciation of inorganic selenocompounds has been demonstrated by simple on-off operation of a focused microwave connected to the HG flow set-up. Electrochemical assays capitalized on the strict control of both the electrolysis potential of thin mercury film-based working electrodes and the acidic medium in the potentiostatic deposition have also been reported for metalloid speciation.

The hyphenation of flowing systems, mainly flow injection, with atomic spectrometric techniques, such as flame or plasma emission spectroscopy (FES or ICP-OES), inductively coupled plasma mass spectrometry (ICP-MS), flame (FAAS) or electrothermal (ETAAS) atomic absorption spectrometry, and cold vapor atomic absorption spectrometry for mercury has proven to be a powerful analytical tool for the determination of ultratrace levels of metals without risk of sample contamination, since an entirely enclosed environment is attained. The benefits of interfacing sequential injection schemes with the discontinuous operation of an ETAAS detector have been recently demonstrated. A noteworthy feature of ICP-MS is the ability of performing isotopic measurements as well as simultaneous multielemental detection, which is of particular importance for fast screening of metal profiles in environmental waters. Yet, the foregoing detection techniques, mainly ICP-MS, inherently show low tolerance to sample constituents present in environmental matrices, including high concentrations of easily ionized elements, salts, and mineral acids (after sample treatment), which might cause severe matrix effects and spectral interferences. In this respect, the isolation of the metal of interest from the matrix components using online separation techniques readily adaptable to flowing-stream methods is called for. Among the different reported schemes, those based on incorporation of column reactors packed with a sort of chelating sorbents (namely, 8-hydroxyquinoline, iminodiacetate, dithiocarbamate, or dithiophosphate) or with nonpolar materials such as copolymeric resins or octadecyl chemically modified silica gel should be highlighted. Co-precipitation/adsorption procedures involving entrapment of the

precipitate/chelate on the inner walls of a knotted PTFE reactor, sorption of volatile species onto coated-graphite tubes of an electrothermal atomizer, and solvent extraction methods including both phase-segmentation or wetting-film modalities should also be featured as worthwhile strategies for online analyte enrichment with concomitant matrix removal.

In recent years, important efforts have been made to adapt electrochemical techniques such as anodic/cathodic stripping voltammetry and potentiometric stripping analysis to flowing systems for monitoring trace levels of transition metals in aqueous samples. Significant progress has also been made in the development of spectrophotometric catalytic methods for trace metal determinations as these approaches are extremely suitable for implementation in portable devices and, hence, for onsite and real-time analysis. Most of such systems are based on well-known catalytic oxidation reactions of phenol or aniline derivatives as well as on the oxidative coupling of amines. Flow injection with inline matrix removal coupled to CL detection is another noteworthy option owing to the high sensitivity and selectivity, wide dynamic ranges, rapid analysis (seconds), robustness, portability, and low costs.

A plethora of speciation schemes for discrimination between different oxidation states and chemical forms (namely, Fe(II)/Fe(III), Cr(III)/Cr(VI), exchangeable/labile/acid soluble aluminum, and inorganic/organic complexes) has been developed exploiting selective complexation reactions prior to spectrophotometric measurements. Multidetector in flow systems with a single sample injection involving the arrangement of several detectors in series, mainly spectrophotometric and AAS detection, has also attracted special attention in speciation studies owing to the inherent advantages of simultaneous determination of species and reduced sample consumption. **Table 2** compiles the noteworthy features of flowing-stream systems hyphenated with various detection techniques for the determination and speciation of metal and metalloid species.

### Organic Compounds

In recent years, the determination of trace amounts of organic compounds in environmental samples for routine water quality control has been performed using flow systems as an economical and straightforward alternative to chromatographic and electrophoretic methods. Great attention is specially paid to the development of FIA/SIA methods for the determination of anthropogenic pollutants such as polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and different families of pesticides

**Table 2** Application of flowing stream systems to the determination of metal and metalloid species in water matrices

<i>Detection technique</i>	<i>Typical elements determined</i>	<i>Water sample</i>	<i>Remarks</i>
Atomic spectrometry	Na, K, Li, Ca	Drinking, tap, ground, surface, natural	An internal standard (namely, Li) is commonly incorporated in samples and standards
FP			A low-temperature flame is used to prevent the excitation of most other metals Wide dynamic range with online dilution and/or preconcentration steps
FAAS	Transition metals, alkaline, alkaline-earth, Al, Pb	Sea, tap, waste, surface, ground, drinking, sewage	Flow rate in the flow system should be carefully selected and compared with the aspiration rate of the nebulizer Sample spends short time in contact with nebulizer and burner, so that the measuring system is readily rinsed between consecutive injections High sample throughput High tolerance to saline matrices Better adapted to SIA technique Improved sensitivity with regard to FAAS due to the rapid atomization of the entire sample
ETAAS	Transition metals, metalloid, Al, Pb	River, surface, lake, drinking, seawater	Analyte isolation/preconcentration with solid-phase extraction, adsorption or (co)precipitation Metalloid determination following entrapping of hydride species in precoated graphite tubes
ICP-AES/ICP-MS	Transition metals, alkaline earth, metalloid, Al, Pb, Bi	Drinking, tap, river, estuarine, wastewater	Fast multielemental analysis and isotope determinations Low tolerance to sample constituents (namely, ionized elements, mineral acids, organic solvents) Analyte isolation with solid-phase extraction, adsorption or (co)precipitation to overcome matrix interferences and enhance sensitivity
HG-AAS/HG-AFS	Metalloids, Pb, Sn, Cd, and Zn	Sea, lake, tap, drinking, surface, wastewater	Different dedicated configurations for gas-liquid separations FIA is preferred in HG-AFS aiming to feed the flame continuously with tetrahydroborate, which is a hydrogen source Implementation of various speciation strategies in flowing systems
CV-AAS/CV-AFS	Hg	River, sea, drinking, tap, surface, wastewater	Enrichment via gold-trap collection Speciation between inorganic mercury and organomercurials
Electrochemical ASV/PSA	Cu, Cd, Zn, Pb, In, Hg	Tap, sea, river, surface, drinking	Multielemental analysis and trace determinations SIA improves the sensitivity using flow reversals and also selectivity exploiting its inherent ability to perform medium exchange procedures
Potentiometry	Alkaline metals, Ag, Ca, Cd, Cu, Hg, Pb	Drinking, natural, tap, effluent	High tolerance to colored and turbid samples Coated tubular electrodes are specially suited for measurements in flowing systems High tolerance to colored and turbid samples Long-term performance due to the short contact time of the sample zone with the active surface

**Table 2** Continued

<i>Detection technique</i>	<i>Typical elements determined</i>	<i>Water sample</i>	<i>Remarks</i>
<i>Spectrophotometry</i>	Earth alkaline, Al, Fe, Mn, Co, Cr, Ni, Cu, Zn	River, lake, well, ground, tap, drinking, waste	Kinetics methods are commonly explored for minimizing interfering effects
			Typical single-element determination A plethora of kinetic catalytic procedures for trace metal monitoring has been developed Sorbent preconcentration sometimes used A variety of speciation schemes based upon the selective complexation of particular oxidation states has been designed
<i>Spectrofluorimetry</i>	Al, earth-alkaline metals, Cu, Fe, Mn, Zn, Hg	Tap, mineral, natural, drinking	Metal traces are determined exploiting the enhancement of the quantum yield of chelating agents via complexation with the analytes
<i>Chemiluminescence</i>	Cu, Co, Fe, Mn, Zn, Cd	Mineral, tap, drinking, seawater, estuarine	Use of the catalytic or inhibitory effect of metal traces on the luminol reaction with hydrogen peroxide or dissolved oxygen Kinetic discrimination and masking strategies are widely used for selectivity improvement Low detection limits are frequently achieved

FP, flame photometry; FAAS, flame atomic absorption spectrometry; ETAAS, electrothermal atomic absorption spectrometry; ICP-AES, inductively coupled plasma-atomic emission spectrometry; ICP-MS, inductively coupled plasma-mass spectrometry; HG, hydride generation; CV, cold vapor; AFS, atomic fluorescence spectrometry; ASV, anodic stripping voltammetry; PSA, potentiometric stripping analysis.

(namely, carbamates, benzimidazoles, and coumarins). For this purpose, chemical procedures based on inhibition of the activity of appropriate enzymes and immunochemical assays have been explored. Though both methods are used for screening of pollutants, the latter exhibits extremely high selectivity to be applied to quantitative determinations in natural waters. More recently, a plethora of luminescence flow injection systems capitalized on the intrinsic fluorescence or (electro)chemiluminescence of the target species has been proposed. The performance of online sorbent-extraction preconcentration procedures or solid-phase based flow-through optosensors provided determination limits down to the risk levels demanded by regulatory authorities. The selectivity of spectrofluorimetric methods is generally improved with the application of different strategies such as constant wavelength synchronous fluorescence, constant energy synchronous fluorescence, or variable angle scanning fluorescence aiming to record characteristic fluorescence spectra. The potential of these methodologies is even enhanced by the application of multivariate chemometric algorithms for treatment of the total luminescence data matrix, with the consequent resolution of multicomponent mixtures.

Surfactants are usually determined as a group of compounds, so that sophisticated chromatographic procedures are not needed. Ion-pair formation between both anionic and cationic surfactants with polar dyes, such as methylene blue and bromocresol purple, respectively, with or without subsequent inline solvent extraction has been assessed using spectrophotometric or spectrofluorimetric detection as shown in **Table 1**. Polyoxyethylene and amine ethoxylate-based nonionic surfactants in environmental waters have been determined by spectrophotometry following polar interactions with chromogenic agents, and by CL detection in the presence of sensitizers, respectively.

The determination of traces of phenolic species has been successfully accomplished by adaptation of batch standard methods based on the oxidative coupling of the analytes with 4-aminoantipyrine. The online preconcentration of the reaction products using solvent extraction, sorption/elution, or sorbent extraction-based optosensing techniques rendered detection limits below the maximum level recommended by EPA Directives. Interferences caused by colored aromatic amines can be successfully circumvented by analyte enrichment on reversed-phase materials prior to their oxidative coupling.

The potentialities of flowing stream systems for the determination of organic pollutants are thoroughly presented in the critical review entitled *Flow Injection Methods of Analysis for Waters: Organic Pollutants* by Danet *et al.* Readers are referred to this exhaustive review and references therein for further details and applications.

## Air Pollution Analysis

The analysis of precipitates (rain and snow), atmospheric water (cloud, fog, and dew), particulate matter, and gaseous compounds is an essential task for air pollution investigations. The application of FIA, and more recently SIA, for such purposes has found considerable interest because many environmental parameters can be determined with high reproducibility and sensitivity. In the analysis of precipitates and atmospheric water attractive features are the high sample throughput and the low consumption of sample, so that microsampling techniques can be fruitfully exploited in monitoring schemes. The micro-analytical capability of FIA has been demonstrated in the determination of hydrogen ion concentrations in single rain drops.

Compounds frequently monitored in precipitate samples are chloride, nitrate, fluoride, hydrogen peroxide, and sulfur species. The determination of sulfur compounds deserves particular attention in atmospheric analysis, especially in the elucidation of the generation, transportation, and conversion of the different species, as well as in understanding the formation of acid rain. Free and combined (namely, hydroxymethane sulfonic acid) sulfite has been commonly determined by flow injection spectrophotometric procedures using chromogenic reagents such as pararosaniline and organic disulfides. Excellent precision, reliability, and selectivity have been achieved through photometric, potentiometric, or spectrofluorimetric approaches coupled to in-line gas-diffusion separation of the generated sulfur dioxide after sample acidification. Iodimetric in-line determinations of sulfite with spectrophotometric or amperometric detection have also been reported. Improved selectivity and sensitivity are readily obtained via enzymatic methods comprising the electrochemical detection of hydrogen peroxide formed during sample passage through an immobilized sulfite oxidase-filled microcolumn. The detection chemistry used for other relevant analytes in precipitates and atmospheric waters is generally the same as that used in water analysis applications. Therefore, the readers are referred to the above sections as well as to Table 3, which summarizes

several flow methods successfully applied to air pollution surveillance.

Filter-collected airborne particulates can be analyzed by flow systems with great advantage since only minute liquid volumes are required. Thus, the amount of solvent used for dissolution, extraction, or digestion can be significantly reduced, consequently creating higher analyte concentration in the eluate, leachate, or extract. Sensitivity enhancement and improved time-resolution of the sampling procedure are then achieved. Flow techniques are also proven excellent avenues to determine anionic species and metal traces from a single filter following sequential treatment with water and acid in a pressurized digestion bomb.

The determination of gaseous compounds (namely, sulfur dioxide, nitrogen oxides, hydrogen fluoride, and ammonia) at atmospheric levels is generally performed ensuing batch trapping/preconcentration in suitable absorber liquids, which are, whereupon, injected in the flow manifold. Yet, a particularly promising approach for gas analysis in the presence of concomitant particulate matter is the exploitation of membrane-based gas sampling coupled to flow systems. In this method, the gas sample is fed through the donor side of a gas-diffusion module, while a liquid absorber is used as a trapping solution. The acceptor liquid is either delivered continuously through the unit toward a downstream detector or is halted for a preset time by stopping the liquid-driver or by implementation of a closed-loop. The latter option not only enables the isolation of the gaseous species from matrix constituents but also the analyte enrichment within the receiver solution. Direct introduction of a gas sample plug into a flowing liquid reagent stream followed by detection of the reaction products formed at the gas-liquid interface has been successfully assessed for both sulfur dioxide and nitrogen dioxide monitoring.

## Analysis of Soils, Sediments, Fertilizers, Animal Feed, and Plant Materials

Flow techniques, mainly FIA, have become consolidated as one of the most efficient and versatile methods in agricultural laboratories. The high sample throughput of FIA meets admirably the requirements of soil laboratories, which are overwhelmed in the planting season. The wide concentration ranges found in agricultural samples, both within the same compound and from one to another, can be easily covered by flowing-stream systems in making use of in-line dilution and preconcentration schemes in

**Table 3** Analytical features of relevant flowing-stream methods applied to air pollution surveillance

Analyte	Sample	Method/derivatization reaction	Detection	Typical working range	Features/sample collection
Sulfur dioxide	Air	Pararosaniline	Photometry	0.01–20 mg m <sup>-3</sup>	Trapping in formaldehyde
	Air	<i>N</i> -Acridinylmaleimide	Spectrofluorimetry	> 2.5 µg l <sup>-1</sup>	Trapping in formaldehyde
	Air	Barium-dimethylsulphonazo-III	Photometry	0.2–14 mg l <sup>-1</sup>	Hydrogen peroxide absorber
	Air	5,5'-Dithiobis(2,2'-dinitrobenzoic acid)	Photometry	> 35 µg m <sup>-3</sup>	Online sampling/gas permeation denuder
	Air	Direct detection	Conductimetry	0.16–3.2 mg m <sup>-3</sup>	Capillary denuder/preconcentration
	Air	Electrogenerated Mn(III) or Ag(II)	Chemiluminescence	0.02–0.64 mg l <sup>-1</sup>	
Ammonia	Air	Direct detection	Potentiometry (NH <sub>4</sub> -ISE)	5.0–100 µg m <sup>-3</sup>	Membrane-based gas sampling
	Air	Berthelot	Photometry	> 0.15 µg m <sup>-3</sup>	Phosphoric acid coated diffusion denuder
Nitrogen oxides	Air	Oxidation of ferroin	Amperometry	1.0–10 mg m <sup>-3</sup>	Direct gas injection
	Air	Griess reaction	Photometry	2.0–500 µg m <sup>-3</sup>	Membrane-based gas sampling
	Air	Direct detection	Coulometry	0.01–2.0 µg m <sup>-3</sup>	Direct gas sampling
Hydrogen chloride	Gas emissions	Direct detection	Potentiometry	1.0–60 mg l <sup>-1</sup>	Use of a Cl-ISE
Volatile arsenic compounds	Air	Arsenite detection after hydrolysis	PSA	0.5–50 µg m <sup>-3</sup>	Gas permeation membrane-based sampling unit
Hydrogen peroxide	Air	Hematin- <i>p</i> -cresol	Spectrofluorimetry	> 10 ng m <sup>-3</sup>	Diffusion scrubber, preconcentration
	Rain	<i>N</i> -Ethyl- <i>N</i> -(sulfopropyl)aniline	Photometry	7.0 × 10 <sup>-3</sup> –1.4 mg l <sup>-1</sup>	
	Rain	Luminol/oxidase (or hematin)	Chemiluminescence	1.0 × 10 <sup>-4</sup> –0.34 mg l <sup>-1</sup>	
Formaldehyde	Air/fog	5,5-Dimethylcyclohexane-1,3-dione/ammonium acetate	Spectrofluorimetry	25–100 µg l <sup>-1</sup>	Interference from sulfite is eliminated by oxidation
Sulfite	Air	Pararosaniline/sulfite	Photometry	0.1–20 mg l <sup>-1</sup>	Masking transition metal ions with chelating agents Gas diffusion separation in an acidified donor stream Membrane-based separation
	Cloud	Pararosaniline/formaldehyde	Photometry	> 13 µg l <sup>-1</sup>	
	Rain	4,4-Dithiodipyridine	Photometry	0.25–10 mg l <sup>-1</sup>	
Nitrate	Rain, fog, snow	Direct measurement	Amperometry	0.08–0.8 mg l <sup>-1</sup>	Membrane-based separation
	Rain	Hydrazine reduction, Griess reaction	Photometry	1.0–10 mg l <sup>-1</sup>	
	Rain	2,3-Diaminonaphthalene/UV irradiation	Spectrofluorimetry	0.03–0.7 mg l <sup>-1</sup>	
Ammonium	Rain	Luminol/chlorine	Electrochemiluminescence	0.014–1.4 mg l <sup>-1</sup>	
	Rain	<i>o</i> -Phthaldialdehyde/2,4,6-trichlorophenyl oxalate	Chemiluminescence	0.01–5.0 mg l <sup>-1</sup>	
Sulfate	Rain	Barium chloride	Turbidimetry	0.1–2.0 mg l <sup>-1</sup>	

Continued

Table 3 Continued

Analyte	Sample	Method/derivatization reaction	Detection	Typical working range	Features/sample collection
Acidity	Atmospheric precipitations	Barium/orthanilic acid	Photometry	0.5–20 mg l <sup>-1</sup>	Single rain drop analysis
	Rain	Barium chloranilate	Photometry	4.0–100 mg l <sup>-1</sup>	
	Rain	Lead-nitrate ISE	Potentiometry	1.0–100 mg l <sup>-1</sup>	
	Rain	Acid-base indicator, titration	Photometry	pH 3–6	
Anionic species (NH <sub>4</sub> <sup>+</sup> , NO <sub>3</sub> <sup>-</sup> , Cl <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> )	Rain	Liquid-membrane ISE	Potentiometry	pH 2.7–5	Microsampling/filter extraction
	Airborne particulate matter	ISE and standard photometric methods	Potentiometry/photometry	µg l <sup>-1</sup> to mg l <sup>-1</sup>

combination with almost any detection technique. Flow methodologies are well accepted since the underlying detection chemistry of established standard methods can be maintained and the extremely low sample volumes required simplify greatly the analytical protocols and reduce the chemical consumption. Since flow techniques are inherently liquid-phase analysis methodologies, constituents in solid samples are usually transferred into the liquid state prior to analysis using appropriate batch pretreatment procedures. Then, the methods described in the foregoing sections for monitoring environmental parameters in waters are equally applicable to the determination of key species in soil, sediments, and plant materials, such as nutrients and metal traces. The coupling of flow systems with atomic absorption spectrometric techniques is especially beneficial for the latter analytes. The high tolerance exhibited to elevated salt and acid contents and differing sample viscosities makes it possible to admit extracts and digests directly without further sample manipulation. Readers are referred to Table 4 for further details related to particular methods devoted to agricultural and solid sample analysis.

In recent years, many efforts have been focused on the design and characterization of sample processing units coupled with flowing systems aiming to enable the direct introduction and treatment of solid samples of environmental origin in an automated fashion. In this respect, various sample pretreatment techniques including electrolytic dissolution, online dialysis/filtration, dynamic-gas extraction, liquid-liquid extraction, ultrasound-assisted extraction, and pervaporation-based procedures have been successfully implemented in flow systems. Very recently, the interfacing of flow injection/continuous flow systems with microwave-assisted extraction, supercritical carbon dioxide extraction, or subcritical fluid extraction treatments has proven useful for the determination of organic pollutants (namely, polycyclic aromatic hydrocarbons, phenolic species, substituted carbamates, and chlorinated biphenyls) as well as metal/metalloid traces in soils, sediments, seeds, and plant tissues as shown in Table 4. These methods usually provide similar efficiencies than US-EPA methods but with dramatic reduction in both the extraction time and sample handling.

It should be also stressed that online dynamic leaching protocols are currently being employed by several researchers as an alternative to steady-state measurements, since kinetic information from the extraction process is thus obtained. With respect to sampling modalities, the exploitation of slurry sampling strategies as well as the implementation of microcolumn reactors packed with solid materials should be underlined.

**Table 4** Analytical features of relevant flowing-stream methods applied to the determination of organic pollutants, nutrients, anionic species, and metal traces in agricultural samples

Analyte	Sample	Method/derivatization reaction	Detection	Typical working range	Features/sample pretreatment
Polycyclic aromatic hydrocarbons	Soil	HPLC/intrinsic properties	Spectrofluorimetry	0.030–0.375 mg l <sup>-1</sup>	Continuous subcritical extraction (micellar medium-water)/reversed-phase preconcentration
	Soil	Intrinsic properties	Fiber-optic spectrofluorimetry	2.0–24 µg per g	Supercritical extraction
N-Methylcarbamates	Soil and sediments	HPLC/intrinsic properties	Spectrofluorimetry	0.2–1.2 mg l <sup>-1</sup>	Online subcritical water extraction
	Soil and fruits	LC/o-Phthaldialdehyde (postcolumn)	Spectrofluorimetry	0.5–10 mg l <sup>-1</sup>	Online ultrasound assisted extraction/inline filtration/solid-phase extraction
Chlorophenoxy acids	Soil	HPLC/intrinsic properties	UV-spectrophotometry	10–50 mg l <sup>-1</sup>	Continuous subcritical water extraction/inline filtration/reversed-phase extraction
Phenol compounds	Soil	Direct injection of eluates	GC–MS	0.05–5.0 µg per g	Online leaching with alkaline solution/ filtration/reversed-phase extraction (semiautomated method)
Ammonium	Fertilizer and soil	pH indicator/gas-diffusion	Spectrophotometry	0.5–20 mg l <sup>-1</sup>	Extraction in a hydrochloric acid medium
Nitrate	Plant tissue	Reduction to nitrite/Griess–Illosvay reaction	Spectrophotometry	> 0.1 mg l <sup>-1</sup>	Hot water extraction
Organic nitrogen (Kjeldahl)	Soil and fertilizer	Direct detection	Potentiometry (NO <sub>3</sub> -ISE)	6.2–62 mg l <sup>-1</sup>	Aqueous extraction
	Plant materials	AgCl microcolumn/displacement reaction	FAAS	1.0–200 µg l <sup>-1</sup>	Kjeldahl digestion
	Fertilizer and plant	Berthelot reaction	Spectrophotometry	0.5–5% (w/w) N	Kjeldahl digestion
	Animal feed, plant, and fertilizer	Gas-diffusion	Conductimetry	0.5–50 mg l <sup>-1</sup>	Kjeldahl digestion
Orthophosphate	Soil	Molybdenum blue	Spectrophotometry	0.05–100 mg l <sup>-1</sup>	Extraction in a hydrogencarbonate medium
Total dissolved phosphorus	Plant tissue	Zinc chloride	Turbidimetry	5.0–60 mg l <sup>-1</sup>	Acid digestion
	Fertilizer and animal feed	Molybdenum blue	Spectrophotometry	5.0–250 mg l <sup>-1</sup>	Online UV photo-oxidation
Sulfate	Soil (or plant)	Barium chloride or lead phosphate	Turbidimetry	1.0–50 mg l <sup>-1</sup>	Extraction in a calcium phosphate medium (or acid digestion)
Sulfide	Soil	Direct detection	Potentiometry	0.3–50 µg per g	Online pervaporation
Boron	Soil and fertilizer	Azomethine H	Spectrophotometry	5.0–50 µg per g	Solid sample introduction, online ultrasonic leaching
pH	Plant	Azomethine H	Spectrophotometry	0.1–6.0 mg l <sup>-1</sup>	Dry-ashing
	Soil	Capillary glass electrode	Potentiometry	pH 4–11	Extraction in a calcium chloride medium
Silicate	Soil	Molybdenum blue	Spectrophotometry	> 30 µg l <sup>-1</sup>	Various extraction procedures
Chloride	Soil	Potentiometric pseudotitration	Potentiometry	1.0–100 mg l <sup>-1</sup>	Aqueous extraction
	Soil	Dialysis separation	Potentiometry (Cl-ISE)	5.0–5000 mg l <sup>-1</sup>	Slurry sampling/online removal of high molecular weight matrix constituents

**Table 4** Continued

<i>Analyte</i>	<i>Sample</i>	<i>Method/derivatization reaction</i>	<i>Detection</i>	<i>Typical working range</i>	<i>Features/sample pretreatment</i>
Chloride, nitrate, and sulfate Potassium	Soil Fertilizer and soil	Capillary electrophoresis Direct detection	Spectrophotometry Potentiometry (K-ISE)	0.1–100 mg l <sup>-1</sup> 1.6–400 mg l <sup>-1</sup>	Online water extraction/filtration Extraction in a sodium acetate solution
Calcium	Animal feed Soil (or plant)	$\alpha$ -Cresolphthalein complexone Glyoxal-bis(2-hydroxyanil)	Spectrophotometry Spectrophotometry	0.05–5% (w/w) Ca < 100 mg l <sup>-1</sup>	Dry-ashing Extraction in a potassium chloride medium (or acid digestion)
Potassium, calcium, nitrate, and chloride	Soil	Multi-ion sensor	Potentiometry	mmol l <sup>-1</sup> level	Extraction in a sodium acetate medium
Potassium, calcium, and magnesium	Plant	Direct injection	FAAS (or FES)	mg l <sup>-1</sup> level	Dry-ashing
Aluminum	Soil	Pyrocatechol violet	Spectrophotometry	0.1–2.0 mg l <sup>-1</sup>	Extraction in a potassium chloride medium
	Plant	Eriochrome cyanine R	Spectrophotometry	0.5–15 mg l <sup>-1</sup>	Acid digestion
	Plant	Direct injection	FAAS	> 75 $\mu$ g l <sup>-1</sup>	Acid digestion/solid-phase preconcentration
Iron	Plant	1,10-Phenanthroline and ascorbic acid	Spectrophotometry	0.1–30 mg l <sup>-1</sup>	Acid digestion
	Soil (or plant)	Direct injection	FAAS	0.4–5.0 mg l <sup>-1</sup>	Aqueous extraction (or acid digestion)
Copper	Plant	Dithiocarbamate or dithiophosphate chelating agents	FAAS	2–900 $\mu$ g l <sup>-1</sup>	Online solvent (or sorbent) extraction of chelates
	Plant	2,2'-Dipyridyl ketone hydrazone and hydrogen peroxide	Spectrofluorimetry	0.2–300 $\mu$ g l <sup>-1</sup>	Catalytic oxidation
	Animal feed	Dialysis with diffusate preconcentration	FAAS	0.025–0.25% (w/w) Cu	Aqueous extraction/injection of particle containing samples
Nickel	Plant tissue	Br-PADAP	Spectrophotometry	0.025–0.5 mg l <sup>-1</sup>	Masking agents and preconcentration on PAN-C <sub>18</sub> column
Chromium	Soil	1,5-Diphenylcarbazide	Spectrophotometry	0.25–10 mg l <sup>-1</sup>	Online ultrasound-assisted extraction/anion-exchange preconcentration
Manganese	Plant (or soil)	Periodate	Spectrophotometry	0.14–1.3 mg l <sup>-1</sup>	Acid digestion (or aqueous extraction)
	Plant	Diphenylcarbazone/O <sub>2</sub> in the presence of triethanolamine	Spectrophotometry	0.1–40 mg l <sup>-1</sup>	Catalytic oxidation
Lead	Plant	Direct injection	ETAAS	8.0–40 $\mu$ g l <sup>-1</sup>	Online acidified subcritical water or ultrasound-assisted digestion (semiautomatic procedure)

Zinc	Plant	NaCl and Zincon	Spectrophotometry	0.1–2.0 mg l <sup>-1</sup>	Dry-ashing/preconcentration of zinc chlorocomplexes
Iron, zinc, manganese, calcium, and magnesium	Plant	Direct injection	FAAS	µg g <sup>-1</sup> level	Mild calcinations/slurry sampling/online dilution for Ca and Mg
Cadmium	Plant	Direct injection	ETAAS	0.1–1.0 µg l <sup>-1</sup>	Online ultrasound-assisted digestion or acidified subcritical water (semiautomatic procedure)
	Fertilizer and plant	Iodide and malachite green	Spectrophotometry	10–100 µg l <sup>-1</sup>	Masking agents/kinetic discrimination/ion-exchange separation
Molybdenum	Plant	Thiocyanate complex	Spectrophotometry	0.05–1.0 mg l <sup>-1</sup>	Liquid–liquid extraction
	Plant (or soil)	Iodide/hydrogen peroxide	Spectrophotometry (or BI)	1.0–40 µg l <sup>-1</sup>	Catalytic oxidation/cation-exchange for metal ion removal
Cobalt	Plant	1-Nitroso-2-naphthol-3,6-disulphonate	Spectrophotometry (or FAAS)	> 3.5 µg l <sup>-1</sup> (or > 0.44 µg l <sup>-1</sup> )	Microwave-assisted digestion/solid-phase extraction
Metalloid species	Plant	Sodium tetrahydroborate	HG-AAS	µg l <sup>-1</sup> level	Acid digestion
	Soil	Sodium tetrahydroborate	HG-AFS	ng l <sup>-1</sup> to µg l <sup>-1</sup>	Online pervaporation/speciation studies
Mercury	Soil	Tin(II) chloride in a hydrochloric acid medium	CV-AAS	1.0–20 µg l <sup>-1</sup>	Microwave assisted digestion or wet-oxidant digestion for total mercury determination
	Soil	Tin(II) chloride in a hydrochloric acid medium	CV-AAS	50–500 ng l <sup>-1</sup>	Online preconcentration/reductive elution
	Soil	Tin(II) chloride in a hydrochloric acid medium	CV-AFS	> 0.01 µg g <sup>-1</sup>	Online acidified subcritical water

## Introduction

Recent analytical literature reveals that a large number of researchers are interested in flow injection analysis (FIA) as an analytical ‘working tool’. One of the early goals of research on FIA was to develop an analytical application that was continuous, and not batch-wise. The alternative to classical analysis was desired to be cost-effective, rapid, simple, and flexible, to allow a ‘universal’ application. The pioneering advances in this period led to new possibilities for implementing various assays and solutions for problems that were very difficult to solve using ‘classical’ batch methods. Once FIA and other automated techniques were in place, research shifted to the development of new analytical procedures.

At present, there is no lack of commercially available FIA instruments that can be interfaced with sampling and data acquisition devices or used in combination with other flow methodologies or more recent flow devices. Many of these instruments (fluorimeters, atomic absorption spectrometers, etc.) offer compact setup suited to specific purposes.

The techniques of flow analysis can be applied to the pharmaceutical and clinical analysis. This entails employing ‘classical’ detectors and chemical strategies. Solution chemistry and ultraviolet (UV)–visible (Vis) spectrophotometry tools are frequently used. The selection of the actual procedure is determined by the type of detector used, and may in general include use of spectrometric detectors, followed by electroanalytical techniques, and separation and biochemical procedures. Special attention is paid to ‘new’ devices used in flow manifolds and to detectors such as chemiluminescence detectors (in which researchers have shown increasing interest). This article discusses these procedures in some detail.

## Introduction

Recent analytical literature reveals that a large number of researchers are interested in flow injection analysis (FIA) as an analytical ‘working tool’. One of the early goals of research on FIA was to develop an analytical application that was continuous, and not batch-wise. The alternative to classical analysis was desired to be cost-effective, rapid, simple, and flexible, to allow a ‘universal’ application. The pioneering advances in this period led to new possibilities for implementing various assays and solutions for problems that were very difficult to solve using ‘classical’ batch methods. Once FIA and other automated techniques were in place, research shifted to the development of new analytical procedures.

At present, there is no lack of commercially available FIA instruments that can be interfaced with sampling and data acquisition devices or used in combination with other flow methodologies or more recent flow devices. Many of these instruments (fluorimeters, atomic absorption spectrometers, etc.) offer compact setup suited to specific purposes.

The techniques of flow analysis can be applied to the pharmaceutical and clinical analysis. This entails employing ‘classical’ detectors and chemical strategies. Solution chemistry and ultraviolet (UV)–visible (Vis) spectrophotometry tools are frequently used. The selection of the actual procedure is determined by the type of detector used, and may in general include use of spectrometric detectors, followed by electroanalytical techniques, and separation and biochemical procedures. Special attention is paid to ‘new’ devices used in flow manifolds and to detectors such as chemiluminescence detectors (in which researchers have shown increasing interest). This article discusses these procedures in some detail.

## Spectrometric Methods

### UV-Vis Spectrophotometric Methods: Homogeneous Systems

Drug analyses based on absorption spectrophotometry usually involve an enzyme catalyzed reaction, ion pair formation (with the aid of liquid-liquid extraction or turbidimetry) or a redox reaction (normally oxidation in solution or an oxidizing bed). Examples of homogeneous applications are listed in Table 1. Zn determination (Table 1) can be used with high selectivity against other metal ions through a differential demasking technique. In the first step, all metal ions (Zn included) are masked by adding KCN; then the Zn(II) is quickly released (kinetic selectivity) using formaldehyde. In another application a double-injection valve is used to insert an enzyme and the analyte fosfestrol into a single carrier stream; then both boluses merge due to dispersion. This approach reduces enzyme consumption.

Most multiparametric procedures are restricted to two active components, and the main challenge is in using different reagents and detection wavelengths. The use of photodiode array spectrophotometers and, more recently, multichannel fiber optic spectrophotometers facilitates this approach. Solenoid valves, to control the flow system, have proved to be very useful in the development of techniques for simultaneous determination of Zn, Fe, Cu, Ca, and Mg in pharmaceutical drugs. Derivative

spectrophotometry should be used to analyze non-complex matrices, with components having overlapped spectra; examples include simultaneous determination of adrenaline and noradrenaline in synthetic mixtures, and sulfamethoxazole and trimethoprim in pharmaceutical formulations using the first-order derivative. Another example is the hydrochlorothiazide-losartan pair, which can be determined in an alcoholic medium using the fourth-derivative spectrum.

A different strategy has been used in the simultaneous determination of ascorbic acid and cysteine. The system uses a double-beam spectrophotometer. When the sample converges with Fe(III) and phenanthroline, the signal obtained corresponds to ascorbic acid. After passing through the flow cell, there is mixing with Cu(II), which accelerates the reaction between Fe(III) and cysteine, with practically no effect on the reaction between Fe(III) and ascorbic acid. When the mixture arrives at the second flow cell, the signal corresponds to the total amount of ascorbic acid and cysteine.

The simultaneous injection of two sample volumes into the same carrier ('single-line double-injection') allows simultaneous determination of Fe(II) and Fe(III) using the colored complex Fe(II)-2,2'-dipyridyl-2-pyridylhydrazone. Fe(III) is reduced online with ascorbic acid before being injected into the carrier. In this way, two peaks are obtained, one from the Fe(II) and other from the total Fe.

**Table 1** Some spectrophotometric (homogeneous systems) applications of FIA

Analyte	Sample	Procedure
Thiamine	Pharmaceutical formulation	Oxidation with hexacyanoferrate(III)
Ascorbic acid	Pharmaceutical formulation	Oxidation with permanganate
Ascorbic acid; vitamin K <sub>3</sub> ; promazine	Pharmaceutical formulation	Oxidation with Fe(III). Determination of released Fe(II) through a colored complex
Cefadroxil; cephalosporins	Pharmaceutical formulation	Hydrolysis in basic medium + oxidation with Fe(III). Determination of released Fe(II) by a colored complex
Fosfestrol; forfomycin	Pharmaceutical formulation and urine	Alkaline-enzymatic hydrolysis or digestion with ammonium persulfate. Determination of orthophosphate through the molybdenum blue reaction
Leucogen	Tablets	Hydrolysis in basic medium
Amoxicillin and ampicillin	Pharmaceutical formulation	Hydrolysis in micellar medium and catalyzed by Cu(II)
Zn(II)	Serum, human hair, and Pharmaceutical formulation	Complex formation with 2,2'-dipyridyl-2-pyridylhydrazone in strong alkaline medium (selective demasking of the KCN complex with formaldehyde)
Creatinine	Urine	Jaffe reaction
Phenylephrine hydrochloride	Pharmaceutical formulation	Ferricyanide + 4-aminoantipyrine
Tyrosine	Urine	$\alpha$ -Nitroso- $\beta$ -naphthol in acid medium
Captopril	Pharmaceutical formulation	Inhibition of the complex Co(II)-2,2'-dipyridyl-2-pyridylhydrazone
Ascorbic acid	Pharmaceutical formulation	Inhibition of the oxidation of pyrogallol red by iodate
Sulfanilamides	Pharmaceutical formulation and blood	As 4,6-dinitrobenzofuroxane derivatives
Doxazosin mesylate	Pharmaceutical formulation	Native absorption in UV at pH 4 in 10% methanol
Se(IV)	Tablets and pig kidney	Catalysis of the gallocyanine reduction by Na <sub>2</sub> S

Methods such as standard addition only provide good results with a relatively simple matrices. One of the main problems when a first-order multivariate model is used is the presence of unknown interferences. Mathematical models have become very important for solving this problem; an example is the determination of five pollutants of the chlorophenol family in urine. The effect of the matrix is minimized by including, in the calibration step, standard samples containing the analytes in the presence of the interfering matrix. The calibration set includes 60 standard samples: 50 samples of chlorophenols in water and 10 of lyophilized urine.

### Heterogeneous Solid-Liquid Systems (Turbidimetry)

The suspension (precipitate) is usually formed by injecting the sample directly into a buffered carrier-reagent stream. The required manifold is essentially a single channel, and the reactor is normally short. This method provides a straightforward and inexpensive alternative for measuring the active components in pharmaceutical dosages using various organic reagents or metal complexes such as counterions. No liquid-liquid separation or subsequent extraction of the organic phase is required. A surfactant can be added to stabilize the suspension and eliminate frequent flushing injections.

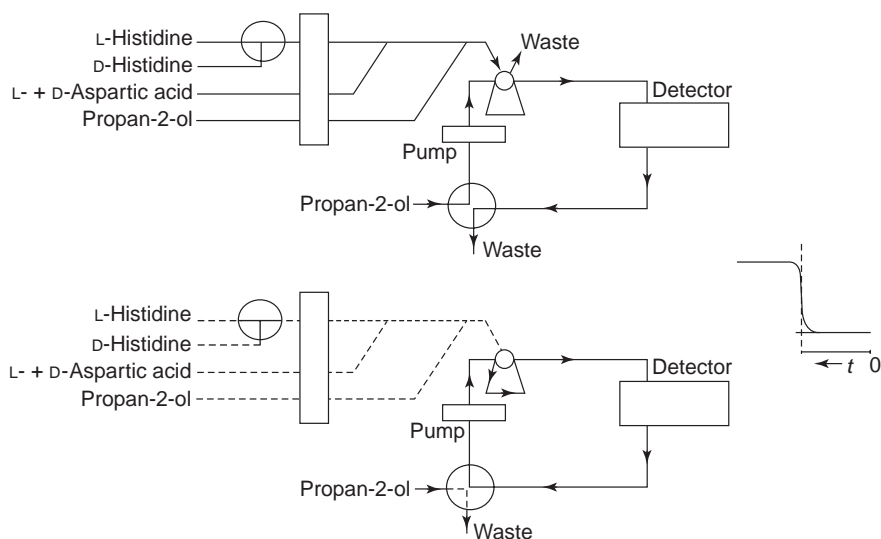

The precipitation of fibrinogen can be used to analyze human blood samples by injecting the sample into a carrier stream of guanidine hydrochloride/titriplex III that merges with ammonium sulfate (the reagent) dissolved in the same buffer.

A final example is depicted in **Figure 1**. The enantiomeric discrimination of l- and d-aspartic acids is based on the inhibition of the process of crystallization of l- and d-histidine. A sample with the pH adjusted at 3–10 (the variation in pH resulted in a plateau) is mixed with l- or d-histidine, and the resulting mixture is injected into a carrier of propan-2-ol and entrapped in a closed-loop circuit. The absorbance versus time plot, which reflects the crystal growth, is recorded at 550 nm. The induction period before the onset of crystallization is used to calculate the analyte concentration. A similar strategy can be used employed for the resolution of structural isomers of arginine and ornithine in pharmaceutical formulations.

### Fluorimetric Methods

Fluorimetry was considered in the 1950s as the ‘natural’ detector for pharmaceuticals, due to its improved selectivity and sensitivity compared with UV-Vis absorption. Recent FIA applications include the determination of diazepam, nitrazepam, and oxazepam in pharmaceutical formulations using acidic hydrolysis and fluorimetric detection. Oxidation with Ce(IV) and measurement of the fluorescence from the released Ce(III), which can be considered as a classical strategy, is an appropriate technique for mixtures of amoxycillin and clavulanic acid where kinetic data are used in combination with partial least-squares multivariate calibration.

Another classical procedure is used for many pharmaceutical compounds: when a primary or secondary amine is present, it reacts with o-phthaldehyde and a thiol compound (like mercaptoethanol or N-acetylcysteine), producing a fluorescent isoindol.

**Figure 1** Flow systems for enantiomeric discrimination of l- and d-aspartic acids.

The secondary amine or amides require a prior reaction with sodium hypochlorite to be converted into a primary amine.

One of the FIA fluorimetric methods for clinical applications involves the reduction of the herbicide diquat using sodium dithionite in a stopped-flow modality; the analyte yields a highly fluorescent product and it can be applied to the analysis of blood serum. Cysteine has also been determined through fluorescence quenching of a complex of Cu(II) with 5-(3-fluoro-4-chlorophenylazo)-8-benzenesulfonamidoquinoline.

### Chemiluminescence Methods

The iterative strategy of investigating the effect of an analyte on luminol or any other effective light emitter, has given way to direct study of the oxidation of the analyte by a strong oxidative reagent. The main goal is to find new chemiluminescent reactions for simpler and more sensitive procedures. The limits to selectivity are imposed by the high chemical activity of the oxidant compared to other components present in the sample. The simplicity of the procedure and the fast kinetics of oxidation provide the additional advantage of a high sample throughput compared with batch procedures.

Most applications are based on the use of potassium permanganate in acidic media. The extensive use of this reagent, besides as an oxidizing agent, relies on its active role in chemiluminescent emission.

Recent studies give new insight into this by revealing the formation of intermediate complexes with the tested organic compounds proflavine and acriflavine. **Figure 2** illustrates this sequence and the light emission in the process.

The application of molecular connectivity to predict the chemiluminescent behavior of substances when they react with common oxidants in a liquid phase is useful for finding new chemiluminescent reactions. A large empirical screening, together with a review of the literature, can provide baseline data of positive and negative chemiluminescent reactions with strong inorganic oxidants. The discriminant function can be applied to different groups of pharmaceuticals and other organic compounds, namely, polyphenols, ergot alkaloids, and pesticides.

Pharmaceuticals displaying chemiluminescent behavior through direct oxidation are depicted in **Table 2**.

The online electrogenerated oxidative agent is theoretically more selective (kinetic selectivity) because it is used with small quantities of oxidant in a small volume, acting over a short period of time.

Indirect methods in chemiluminescence have long been used in pharmaceutical applications. The methodology is based on the light emission of some (very few) effective light emitters: the presence of the analyte affects the light emission by enhancing or inhibiting the yield. The use of the 'universal' light emitter luminol is still widely used (**Table 3**). The majority of listed procedures are based on the oxidation of luminol by hydrogen peroxide.

**Figure 2** Intermediate complexes in the oxidation of proflavine and acriflavine by potassium permanganate.

**Table 2** Chemiluminometric procedures using direct oxidation of the analyte

	Oxidant	Drug (sample)
Reactive in solution	Permanganate	Tetrahydropalmatine (tablets); reserpine (Ph); rescinnamine (Ph); yohimbine (Ph); medazepam (Ph); cefadroxil monohydrate (Ph and BF); salicylamide (Ph and urine); perphenazine (synthetic formulations); dipyrindamole (tablets and injections); etilefrine hydrochloride (Ph and BF); isoxsuprine hydrochloride (Ph and BF); prenalterol hydrochloride (Ph and BF); amidopyrine (Ph); pipemidic acid (Ph); ethamsylate (Ph); folic acid (Ph); sulphonamides (Ph); chloramphenicol (Ph)
	Ce(IV)	Captopril (tablets); tiopronin (Ph); penicillamine (Ph); phenothiazines (fluphenazine; levomepromazine; methotrimeprazine; trimeprazine tartrate) (Ph, urine, and plasma); furosemide (Ph); hydrochlorothiazide (Ph); analgin (tablets); phenacetinum (tablets); folic acid (Ph)
	Ce(IV)/sulfite	Fluoroquinolones (ofloxacin; norfloxacin; ciprofloxacin; lomefloxacin) (Ph); benzamides (sulpiride; sultopride; tiapride) (Ph and BF); ofloxacin (Ph).
	Tris(2,2'-bipyridyl) ruthenium(II)/Ce(IV)	Fluoroquinolone (ofloxacin, norfloxacin, ciprofloxacin) (Ph); thioxanthenes (zuclopenthixol, flupentixol, thiothixene) (Ph and BF); flufenamic and mefenamic acid (Ph)
	Tris(2,2'-bipyridyl) ruthenium(III)	Ranitidine (Ph); salbutamol (Ph)
	Periodate	Isoniazide (tablets); lincomycin hydrochloride (injections)
	Peroxides	Tetracyclines (tetracycline, chlortetracycline, oxytetracycline) (Ph); vitamin B <sub>12</sub> (Ph); albumin (Ph)
	Sodium hypochlorite	Persantin (injections and tablets)
	Hypobromite (generated <i>in situ</i> )	Urea (urine)
	Dissolved oxygen	Menadione (Ph and BF)
	Hexacyanoferrate(III)	Thiamine (tablets); isoniazide (Ph); ergonovine maleate (Ph); ergotamine (Ph)
	N-Bromosuccinimide	Amiloride (Ph); streptomycin (Ph); epinephrine (Ph)
Electrogenerated	Co(III)	Gentamycin (Ph); pipemidic acid (Ph); sodium phosphate dexamethasone (injections)
	Mn(III)	Adreson (tablets and injections); quinine (Ph); captopril (Ph)
	Ag(II)	Captopril (Ph)
	Bromine	Tetracyclines (tetracycline, oxytetracycline, chlortetracycline) (Ph)

Ph, pharmaceutical formulations; BF, biological fluids.

Lucigenin is the next most frequently used emitter for the determination of isoprenaline or kanamycin by inhibition of the lucigenin–hydrogen peroxide–cobalt(II) system, and also for the determination of the trace amounts of dopamine. The chemiluminescent determination of protein in a micellar medium using FIA employs offline labeling of albumin by sonicating a mixture of 1 ml of albumin in NaHCO<sub>3</sub> (pH 11.5) and fluorescamine in acetone for 1 min at room temperature.

The wide spectrum of chemiluminescent determination of pharmaceuticals also includes the use of immobilized reagents. However, the luminescence obtained through procedures other than those involving solved oxidants is not widely used, except in electroanalytical procedures.

Electrogenerated chemiluminescence in a flow cell containing a working electrode can be applied to the detection of codeine, heroin, and dextromethorphan. For the antibiotic cefadroxil, the flow cell is equipped with a Pt disk working electrode.

### Photochemical Methods

The easy control of photoreaction by regulating the flow (the usual photoreactor is a polytetrafluoroethylene (PTFE) tubing helically coiled on the lamp) makes it a very effective procedure. The most frequently used irradiation sources are mercury low-pressure lamps radiating in the UV range. Some authors propose the use of light in the visible range, and a Nd:YAG laser lamp has been used to irradiate chloroquine at 335 nm. The variety of commercially available lamps permit work with different 'sensitivity' and 'selectivity' (power and wavelength, respectively) levels of this 'analytical reagent'.

Fluorimetric detection of some pharmaceuticals is based on coupled irradiation–fluorimetry (Table 4). UV–Vis absorption techniques also use photolysis as the sole 'chemical' reaction of the sample before the determination or, in other cases, as an aid to a chemical derivatization reaction (Table 4).

**Table 3** Chemiluminescence analytical procedures based on the light emission of luminol

	<i>Drug (effect)</i>
H <sub>2</sub> O <sub>2</sub>	Vitamin B <sub>12</sub> (catalysis); ascorbic acid; morphinan alkaloids (morphine, sinomenine, and codeine); pyridoxine; sodium nitroprusside; sulbactam sodium (enhanced CL); clavulanic acid (enhanced CL); captopril (enhanced CL)
Potassium periodate	Isoniazide (enhanced CL); ascorbic acid; adrenaline and isoprenaline(immobilized); captopril
Fe <sup>2+</sup> ( <i>in situ</i> generated Fe(III) in HClO <sub>4</sub> )	Chlorpromazine, trimeprazine, and trifluoperazine (all emitting light by reduction of Fe(III); the Fe(II) was the catalyst)
Potassium permanganate	Paracetamol (inhibition); oxymetazoline (inhibition)
Potassium hexacyanoferrate(III)	Isoniazide (inhibition); menadione sodium bisulphite; rutin (inhibition); calcium debesilane (inhibition)
Hypochlorite electrogenerated	Etamsylate (inhibition); catecholamines (inhibition); isoniazide (sensitizing); methotrexate; cytarabini
Hypobromite electrogenerated	Isoniazide

**Table 4** Photodegradation analytical flow procedures for pharmaceuticals

<i>Detection</i>	<i>Drug (matrix)</i>	<i>Reagent or medium</i>
Fluorescence	Sulfadiazine (pharmaceutical preparations)	Aqueous solution
	Phenothiazine derivatives (urine)	In water or in ethanol
	Chlorpromazine (pharmaceutical preparations)	In slightly acidic medium
	Reserpine (tablets)	In acetate buffer of pH 3.4 and acetone
	Paracetamol (pharmaceutical preparations)	In presence of acetone and borax buffer at pH 9.6 or in Na <sub>2</sub> CO <sub>3</sub> /NaOH medium
	Sulfamethazine (pharmaceutical preparations)	By using sodium sulfite as sensitized and borate buffer at pH 8
	Menadione sodium bisulfite (pharmaceutical preparations)	In a mixture of acetone, NaOH, and sodium sulphite
	Thiamine (pharmaceutical preparations and serum)	In alkaline medium and presence of sodium sulfite
	Tianeptine and some of its metabolites (pharmaceutical preparations)	In aqueous solution containing 30% propan-2-ol at pH 2.3
	Ascorbic acid (pharmaceutical preparations)	With thionine blue in phosphate buffer at pH 3
Spectrophotometry	Nitroprusside (serum and pharmaceutical preparations)	With M-phloxin buffered at pH 6 with phosphate and in the presence of EDTA
	Sulfamethoxazole (tablets)	In ethanol
	Thioridazine (pharmaceutical preparations)	In nitric acid
	Thiamine (pharmaceutical preparations)	In HCl
	Diethylstilbestrol (pharmaceutical preparations)	In aqueous dipotassium hydrogen orthophosphate medium
	Riboflavine and riboflavine 5'-phosphate (multivitamin preparations)	With dianisidine and Mn <sup>2+</sup>
	Ascorbic acid (tablets)	With methylene blue
	Lactate (serum and pharmaceutical preparations); oxalate, citrate, and tartarate (pharmaceutical preparations)	By means of Fe(III); the resulting Fe(II) was determined using ferroine
	Vitamin K <sub>3</sub> (pharmaceutical preparations); chloramphenicol (pharmaceutical preparations); lactate (serum and pharmaceutical preparations); citrate (pharmaceutical preparations); riboflavine and riboflavine 5'-phosphate (pharmaceutical preparations); DNA (rabbit tissues); glucose (serum and urine)	Luminol
	Chloramphenicol (pharmaceutical preparations); sulfamethoxazole (pharmaceutical preparations); thiamine (pharmaceutical preparations)	Permanganate in acid medium
Biamperometry	Hydrochlorothiazide (pharmaceutical preparations)	Ce(IV) in acid medium
	Chloramphenicol and metronidazole (pharmaceutical preparations)	By an indirect procedure; reaction in acidic media and iodine release
Amperometry	Ascorbic acid (tablets)	With methylene blue
	DNA	Modified carbon paste electrode
AAS	Organoarsenic (urine)	Basic medium

The use of irradiation combined with chemiluminescence is not unusual; the idea is to use the photofragments as 'chemiluminescent analytes' to be oxidized directly or to form part of a luminol system. The photoproduct of sparfloxacin forms a complex with  $Tb^{3+}$ ; the complex sensitizes the chemiluminescence intensity of the Ce(IV)/sulfite system. Electrochemical detectors have also been employed to detect the resulting photofragments (Table 4).

### Atomic Spectrometric Methods

Atomic absorption spectrometry (AAS) can be used for the analysis of clinical samples, which often involves the determination of presence of metals in fluids and tissues, whether for toxicological investigation or for therapeutic indications. Most of these studies are carried out on urine, although determinations are also made in whole blood, blood serum, hair, biological tissues, or saliva (Table 5).

Other techniques used in this context include graphite furnace analysis, hydride generation, and cold-vapor absorption. Other applications involve the indirect FIA-AAS determination of some drugs in pharmaceutical formulations based on a prior reaction or precipitation, or redox or complex formation. Examples are shown in Table 6.

### Electroanalytical Techniques

The development of potentiometric detectors based on ion-selective electrodes continues to expand the scope of clinical and pharmaceutical applications of FIA. The small surface area of the sensor avoids adsorption problems and extends the service life of the electrode. The surface can be readily renewed periodically by alternating the washing cycles with the sampling cycles. The selectivity thus achieved is usually very good as it relies on differences in the

responsiveness of the detector to different components of a sample.

Some of the advantages of this type of sensor were already anticipated in one of the earliest FIA applications, namely, the joint determination of sodium and potassium in serum. Important parameters include the angle at which the carrier impinges on the active surface, the electrode placement angle, the immersion depth and surface area, the flow rates, and the cell void volume.

### Potentiometry

Several electrodes are used for the direct determination of pharmaceuticals. For example, an electrode is prepared using a polyvinyl chloride (PVC) membrane and bis(2-ethylhexyl)sebacate has been applied to tetracyclines in pharmaceutical formulations. The system has also been used to obtain the dissolution profile of some tetracycline formulations. A membrane for the determination of dopamine was synthesized using a  $CuSO_4$ -poly(ethylene-co-vinyl acetate) mixture in tetrahydrofuran, and the resulting solution was dropped into a tubular graphite-epoxy electrode. The drug was oxidized by Cu(II) immobilized on the membrane.

The miniaturization of sensors is an advantage for *in vivo* measurements. A miniaturized ion-selective sensor chip for potassium, mounted in a catheter or cannula and integrated onto an Si chip containing valinomycin with a Ag/AgCl reference electrode coated with a poly(hydroxyethyl methacrylate) layer, has been used in *in vivo* determination of K in blood or serum.

Indirect potentiometric measurements of pharmaceuticals can be performed by different methods,

**Table 5** FIA-determination of metals in biological and pharmaceutical samples

Sample	Metal
Serum	Ni, Se, Sr, Sn, Zn, Pb, Mg, Cu, Fe, Li, Cu
Whole blood	Hg, Se, Bi, Cd, Ni, Sb, Mn, Zn, Co, Pb, Cu
Urine	As, Gd, Co, Se, Ni, Bi, Sb, Ge, Pb, Cd, La, Ca, Mg, Li, Hg, Cu
Hair	Hg, Se, Cd, Ni, Sn, Pb, Cr, Co, Mo
Saliva	Hg
Pharmaceutical preparations	Cu, Fe, Zn, Pb, Bi, Cr, Co, Cd, Ni, As, Hg, Se

**Table 6** FIA indirect determination of pharmaceuticals (precipitation, complex formation, and solid-phase reactions) using AAS

Analyte	Reagent
Captopril and analgin	Cu(II)/KSCN buffered at pH 5.5
Norfloxacin	Cu(II)/sulfosalicylic acid in buffer at pH 5
Amoxicillin	Permanganate and barium chloride in basic medium
Quinine	Sodium tetraphenylborate in basic medium
Saccharin	Ag(I)
Papaverine and cocaine	Reinecke's salt
Ascorbic acid	Cr(III) in acid medium (redox)
Cyanide	Ag(I); solid-phase reactor
Vitamin B <sub>6</sub>	MnO <sub>2</sub> at pH 4–5; solid-phase reactor
Salicylic acid	Cu(II); solid-phase reactor
Ondasetron	Pb(II); solid-phase reactor

such as flow titration or by measuring the product of a prior chemical process. A flow titration for ascorbic acid is based on the reduction of iodate and determination of the released iodine using a flow-through ion-selective electrode. The FIA titration of epinephrine in pharmaceutical formulations is based on a PVC tetraphenylborate tubular electrode.

An example of the second modality is the hydrolysis of penicillin through a reactor containing immobilized penicillinase in which penicillinoic acid is detected using a pH electrode.

The combination of spectrometry and potentiometry enables multiple measurements, such as that of calcium and pH in serum using the spectral absorption of the former and the potentiometric signal of the latter. Also, stripping potentiometry has been employed for measuring mercury in urine, sediments, and biological materials using a gold electrode. Other inorganic analytes that have been studied include permanganate in pharmaceutical preparations (by incorporating an electrode prepared by dissolving a gold(I) complex), 2-nitrophenyl octyl ether, and PVC in tetrahydrofuran.

### Voltammetric Methods

The adsorption–preconcentration sequence has been applied to the determination of chlorpromazine in the presence of nonabsorbable species with similar redox potentials at concentrations up to 100 times higher than that of the analyte. Similarly, doxorubicin has been determined in urine samples subjected to no pretreatment; the drug is rapidly adsorbed over various carbon electrodes, where it is oxidized at fairly low potentials (0.57 V) and pH 4.5.

Te(IV) in urine has been determined through differential pulse voltammetry; the electropolymerization of 3,3'-diaminobenzidine on a gold surface gives a film of poly(3,3'-diaminobenzidine), which can form a complex with the Te(IV).

The measurement of tin in human hair, canned fruit juice, and spiked sea water has been carried out using flow injection anodic stripping voltammetry. The system uses an epoxy–carbon powder 8-hydroxyquinoline composite electrode and nonelectrode preconcentration in an open circuit in which Sn(II) is accumulated in the wall-jet electrode.

There have been recent reports of a glucose biosensor based on electroenzyme-catalyzed oxidation of glucose using a horseradish peroxidase–glucose oxidase lying on polymeric membrane. The biosensor has been used with human serum and pharmaceutical samples.

### Amperometric Methods

Most amperometric detection relies on enzymatic activity. A biosensor based on encapsulated glucose oxidase within a sol–gel glass has been used to determine glucose in an electrolytic solution for intravenous administration and human serum samples.

The isocitrate dehydrogenase activity in human serum has been determined by kinetic assay at 37°C, with isocitrate and NADP as substrates. The rate of formation of NADPH was amperometrically monitored and the selectivity was improved by covering the active surface of the electrode with a poly(*o*-phenylenediamine) film. The electroimmobilization of the enzyme monoamine oxidase into a polypyrrole film around a platinum electrode has been used to determine the antidepressant drug fluoxetine in pharmaceutical preparations.

Ascorbic acid in pharmaceutical preparations has been determined using a gold electrode made from compact disks (CDs) modified with platinum. The CDs consisted of a polycarbonate base on which a thin layer of photosensitive organic dye had been deposited. On this layer a mirror-like film of gold was fixed. Due to the low price of the CDs, each sensor can be used as gold electrode. A slice of the CDs was modified by electrochemical deposition of Pt.

## Online Separation Techniques

### Liquid–Liquid Extraction

Earlier FIA liquid–liquid extraction assemblies were limited to a few types of segmenters for merging solutions (aqueous and nonaqueous) and phase separators; most were home-made from glass, and the phase separation did not reach satisfactory levels. This led to the development of a variety of new and more sophisticated segmenters and phase separators by combining different types of models and hydrophilic and hydrophobic materials. This in turn provided improved phase separation when gravity was combined with hydrophobic PTFE membranes allowing 'filtration' of only the nonaqueous phase. This methodology has been frequently used for complex samples, e.g., in clinical studies. Other research lines have been devoted to avoiding the phase-separation step by 'electronic separation' or by homogenizing both phases.

A 'dual-conical gravitational phase separator' has been proposed for determining Cu and Pb in urine. A citrate-buffered medium (pH 3) serves to form analyte–ammonium pyrrolidinedithiocarbamate neutral complexes. These are then extracted into isobutyl ketone, and the organic phase separated by means of a dual-conical gravitational phase separator and

stored in a PTFE holding coil. Subsequently, an aqueous back extraction is performed with Pd(II) ions as the stripping agent using a second separation unit.

For the measurement of theophylline and diphenhydramine in pharmaceutical preparations, the sample is injected into an aqueous phase, and a hexanol-water segmented flow is established in the extraction coil. The wetting film of the organic phase forms on the walls of the PTFE tubing, reducing the linear velocity of the organic flow, and the differential flow velocities yield a separation in time between the unextracted and extracted components. The segmented flow is merged with a methanol stream and enters a mixing coil for homogenization before passage through the spectrophotometric flow cell.

Among the most frequently used organic solvents is chloroform, used for the determination of many anions in various samples: free cyanide and thiocyanate ions in human saliva; chlorophenols in urine; and Bi(III), ethambutol hydrochloride, diclofenac, phenothiazine derivatives, imipramine, warfarin, flufenamic acid, and ethylmorphine in pharmaceutical preparations. Another proposed solvent is dichloroethane, used for the determination of bromhexine in serum; and imipramine, ambroxol, berberine, bromhexine, neostigmine, 8-chlorotheophylline, and diphenhydramine in pharmaceutical samples.

## Dialysis

The dialyzer unit employed in FIA is formed by two plates of inert material (methacrylate) that are screwed to each other through a crescent bore in each. To decrease dispersion, the channels are often packed with inert glass beads. In this way, the sample is injected into the donor stream, crosses the dialyzer, and is brought into contact with a membrane that is crossed by the analyte. The dialyzer can be nesting at virtually any point in the flow assembly, according to the requirements of the method, and planar spiral arrangements have been proved to be the most efficient.

Several systems include one or two reactors (usually enzyme reactors) to remove interferences. The determination of Zn(II) in multivitamin tablets employs an electro-dialyzer fitted with a passive neutral membrane to enhance mass transfer together with the removal of interferences. Two electrodes are placed at the sides of the membrane, and the applied potential forces the analyte to the acceptor stream.

Methods based on converting an analyte into a gaseous phase to be separated through membranes are used, e.g., ammonia in urine is released by

merging the sample solution with the alkaline stream and then it crosses membrane to an acidic acceptor. The same separator has been used for creatinine and carbon dioxide in blood after the sample flows through an enzymatic solid-phase reactor that releases ammonia.

The earliest FIA applications of dialysis were focused on developing microdialysis units for *in vivo* measurements such as the determination of glucose using a biosensor connected to a microdialysis probe. Other *in vivo* and microdialysis processes have been developed to study the bovine serum albumin (BSA) binding of streptomycin sulfate using a luminometer detector; to monitor calcium in blood and for fluorimetric detection; and to monitor calcium in blood through chemiluminometry.

The dialyzer also serves as a means of either removing interferences or diluting the sample, as has been shown for the photometric determination of phosphate and chloride and sulfate in blood serum and urine. For electrochemical determination of glucose in parenteral solutions, two dialyzer units are inserted, the first one for diluting the matrix and to eliminate interferences and the other for the enzymatic reaction with glucose oxidase circulating through a closed circuit to minimize the required reagent (Figure 3).

## Precipitation

As mentioned previously, the simplest possible way of inducing precipitation in FIA is to use a single-channel manifold and inject the sample into a buffered carrier-reagent stream, typically containing a metal ion. The manifold includes a filtration device for measuring the 'excess' of reagent, which will give rise to a negative transient signal; or the precipitate should be dissolved to measure the product of the reaction.

Off-line precipitation of captopril in pharmaceuticals using the Cu(II)-SCN<sup>-</sup> system buffered at pH 5 gives a suspension to be injected into a buffered carrier that is transferred to a conical filter packed with cotton, and further diluted in the excess Cu(II) in a mixer prior to air/acetylene flame AAS. Systems analogous to online precipitation-dissolution can be found for saccharinate in pharmaceuticals; Co, Ni, and Cd in urine; and immunoglobulin G in serum.

Reverse FIA has been proposed for papaverine and cocaine in pharmaceutical preparations. The reagent Reinecke's salt is injected into the HCl carrier, and the observed FIA peak is due to chromium. The peak difference (HCl carrier or sample carrier) represents the precipitated chromium and the analytical output.

**Figure 3** Determination of glucose in parenteral solutions.

## Solid-Phase Reactors and Online Sample Conversion

A reactive bed can be prepared using 'insoluble' materials, provided they have the required mechanical and chemical resistance; a more frequent procedure is to anchor the reagent to a solid support. The reactor can be nested at different points along an FIA manifold, depending on the purpose they serve. Some examples below are illustrative of some of the operational modes used in this context.

On redox- or complex-forming reaction with a solid-phase reactor, some drugs release a constituent metal to an extent proportional to the concentration of the drug in the sample. The released ion can thus be directly monitored, usually through AAS, or by using any other detector, after a chemical reaction.

The bed-reactor can act as a source for the reagent; a reverse FIA as in **Figure 4** has been used for thiamine, rutin, and riboflavin measurement in pharmaceuticals and in urine. The column was prepared with luminol and periodate on an anionic exchange resin. The drug content was related to the diminution or increase of the emitted light. The resorcinol chemosensor is another example, in which the light emission was generated by the reaction of  $K_3Fe(CN)_6$  and luminol in an alkaline medium with the reagents immobilized on an anion-exchange resin and eluted by sodium phosphate. Similar flow systems can be found for folic acid and rutin in human urine and pharmaceuticals.

The same resin has been employed to fabricate a sensor. Immobilized resin is packed in a glass tube ( $50 \times 3$  mm inner diameter) placed in front of a photomultiplier tube. The system can be used for the determination of isoniazide, adrenaline, and isoprenaline in pharmaceuticals by insertion of the sample in a carrier of water.

The use of a sensor with a solid-phase reactor in the same cell minimizes the analyte dispersion. The solid bed (resin or a gel ion exchange) contains the immobilized reagent or can be used to retain the analyte, either directly or after forming a complex or an ion-paired compound, which is retained. These

**Figure 4** Flow assembly with a solid-phase reactor as a source for the reagent.

sensors have also been used for resolution of mixtures such as paracetamol, caffeine, and acetyl salicylic acid.

Sequential spectrophotometric measurements of two drugs (ascorbic acid–thiamine, acetyl salicylic acid–thiamine, or paracetamol–salicylamide) and fluorimetric measurements (warfarin–thiabendazole) have been performed using two solid-phase reactors: first, a precolumn retains one of the analytes and the nonretained one is monitored in a flow cell containing a solid-phase reactor; anionic exchange for the spectrophotometric measured couples or C18 bonded silica for the fluorimetric measurements. The next step is to elute the formerly retained analyte to be monitored.

The major difficulty of using an 'insoluble' reagent lies in the particle sizes of commercially available chemicals. A reactor of  $CoCO_3$  prepared by entrapping the salt into a polymeric material and filling a packed-bed reactor has been employed for cysteine determination. The same strategy has been used in the measurement of many drugs: the immobilization of  $FePO_4$  as a source of  $Fe(III)$  allows determination of nalidixic acid, pipemidic acid, thioridazine, or chlorpromazine using a merging-zones flow system. A reactor containing cupric salts allows spectrophotometric determination of salicylic acid; a reactor of  $AgCl$  or  $AgI$  is used for ammonium or cyanide ion, respectively. The trapped oxides of manganese and lead allow determination of isoniazide, phenothiazines and adrenaline, and metamizol and ondasetron, respectively, through AAS, spectrophotometry, or fluorimetry.

Immobilization on a membrane is occasionally an effective alternative to solid-phase reactors. Thus, a

cationic fluorescent probe of hexadecyl-acridine orange is immobilized on a PVC membrane containing valinomycin with the membrane fixed to the inner walls of the flow cell. In this way, potassium ion is selectively determined in plasma samples. A flow-through bulk optrode membrane that incorporates 1-(2-pyridylazo)-2-naphthol in a plasticized PVC membrane entrapped by a cellulose support is useful for the determination of Zn(II) in pharmaceutical samples.

### ***In Vitro* Availability or Dissolution Profiles**

The *in vitro* availability test, also known as the solution profile of a pharmaceutical formulation, is an established mandatory test in international pharmacopoeias.

The original idea of implementing FIA in a dissolution assembly was to obtain 'individual' profiles versus the 'global' profile test mandatory in pharmacopoeias. The flow assembly, prepared for the determination of an active principle, is connected to the solution vessel, and the resulting 'curve' (a set of increasing FIA peaks) is the concentration versus time of a single active principle. An FIA system for the determination of thioridazine based on the oxidation of the drug by Fe(III) obtained from a solid-phase reactor has been used to obtain the dissolution profile of tablets containing this drug.

Any kind of detector other than the UV-Vis spectrophotometer, implementing the FIA assembly, is useful for obtaining the 'individual profile' of a drug in a pharmaceutical formulation. The dissolution profile of tablets containing ondasetron has been obtained using AAS, monitoring the Pb(II) released from a solid-phase reactor when the ondasetron goes through it. Chemiluminescence has been used to obtain the dissolution profile of sulfamethoxazole by oxidation with permanganate after photodegradation of the drug.

The simultaneous dissolution profile of two compounds with overlapped spectra has been solved using different mathematical approaches. Derivative spectrophotometry is a solution used for the couples sulfadiazine-trimethoprim, amitriptyline-perphenazine, sulphamethoxazole-trimethoprim, amoxicillin-bromhexine, and amoxicillin-clavulanic acid. This strategy has been used to obtain three dissolution profiles, namely, the 'standard' (global) profile and two individual profiles such as sulphamethoxazole-trimethoprim or hydrochlorothiazide-captopril.

The simultaneous monitoring of three drugs requires chemometric methods. The fluorimetric determination of vitamins B<sub>1</sub>, B<sub>2</sub>, and B<sub>6</sub> from multicomponent solid

preparations has also been used to monitor the dissolution of these drugs.

A microdialysis sampling has been used for multivessel dissolution testing of isoniazide tablets. The dialyzer is produced using regenerated hollow cellulose dialysis fibers, and the detection is at 254 nm.

## **Biochemical (Enzyme and Immunoassay) Methods**

### **Enzymatic Assays**

The earliest FIA enzymatic analysis involved the use of a solution or an immobilized enzyme reactor (IMER). At present, most FIA users prefer the marriage of convenience FIA-IMER, clearly due to the advantages presented by this modality, namely, high reactivity and high reproducibility. Further, the enzyme is regenerated via a catalytic cycle, in variations of the enzyme activity are reflected on transient FIA outputs, and small variations in the system behavior (pH, flow rates, temperature, or traces of inhibitors or activators) are not seen in the results.

An assay for angiotensin has been developed with the aid of FIA-IMER and by converting enzyme-inhibitory activity. The quantification of hippuric acid liberated from hippuryl-histidyl-leucine with the aid of the d-amino acid oxidase in the carrier solution resulted in a constant level of H<sub>2</sub>O<sub>2</sub> until the reaction was inhibited by benzoate produced by the action of aminoacylase on hippuric acid. This reduction was monitored amperometrically, allowing indirect measurement of the hippuric acid.

The simultaneous determination of galactose and galactose-1-phosphate in dried blood uses an enzyme-immobilized column and has been applied to preliminary neonatal mass screening for galactosemia. Galactose dehydrogenase and alkaline phosphatase have been immobilized into a gel and packed into a column.

The immobilization can be performed with a modality different from that of the reactor filled with the immobilized enzyme. The spectrophotometric control of hemodialysis treatment is based on an optical flow-through biosensor based on Prussian Blue film with chemically linked urease forming a monomolecular layer of the enzyme. This pH-enzyme optrode-FIA system has been used for the selective determination of postdialyze urea in real clinical samples.

A novel immobilization device for an FIA system is an enzyme reactor fabricated from an anisotropically etched Si chip and a glass plate (determination of

glucose). The V-shaped groove side of the Si wafer is anodically bonded to a glass plate to produce an Si capillary. A solution of 3-aminopropyltriethoxysilane in toluene is passed through the capillary, followed by heating overnight at 115°C. The capillary is treated with glutaraldehyde at pH 7.1 for 1 h and then filled with glucose oxidase at pH 7.1 overnight for immobilization of the enzyme. The enzyme reactor is then incorporated into an FIA system.

The classic peroxidase immobilization has been extended to electrodes, e.g., determination of hydrogen peroxide based on a peroxidase/ferrocene-embedded carbon paste electrode covered with a Nafion-coated cellulose acetate membrane. The system was successfully used for glucose and urate in serum.

In pharmaceutical formulations, acetylcholine can be determined by employing a detector where portions of the analyte are injected into a carrier at pH 7.4 and passed through a solid-phase reactor containing immobilized acetylcholinesterase on glass beads. The solution merges with a stream of H<sub>2</sub>SO<sub>4</sub> and passes through a PTFE membrane diffusion cell. The acetic acid that diffuses through the membrane is carried by the acceptor water to the detector cell.

Immobilization of enzymes in the detector flow cell is of paramount importance in the performance of electrodes. The fabrication and performance of a reticulated vitreous carbon-based tyrosinase flow-through electrode, in which the enzyme was covalently immobilized, was tested as an amperometric detector for phenolic compounds. The measurement of uric acid in plasma can be carried out through closed-loop FIA using a co-immobilized enzyme flow cell and chemiluminescence detection.

### Immunoassays

The specific interaction antigens (analytes) and antibodies (reagents) used for analytical methods generally known as immunoassays are reflected quantitatively by changes in the activity or signal yielded by an appropriate label. The inception of FIA in the immunological field results in faster and more reproducible assays. Examples are given in Table 7.

Since antibody-antigen binding does not produce a detectable signal by itself, several techniques involve a tag such as an enzyme, radioisotope, or fluorophore to monitor the reaction with a variety of optical and electrochemical detectors. One group of detectors generally uses fluorescence and chemiluminescence while another employs amperometry and potentiometry. Electrochemical immunoassays are emergent alternatives to existing immunochemical

methods, especially for opaque or optically dense matrices.

Heterogeneous flow systems are generally preferred as they show a higher sensitivity and flexibility than the homogeneous ones. A solid-phase reactor binds the species of interest and allows the rest of the matrix to pass through the reactor; this is the separation step. Then, the bound analyte must be removed without affecting the activity of the reaction surface of the immobilized antibody. Both characteristics, the antibody affinity and the detectability of the label, are essential in the design of the final heterogeneous immunoassay system.

Chemiluminescence continues to be a very selective and sensitive detection tool in FIA immunoassays. The main component in the most commonly used heterogeneous systems is an immunoreactor column, consisting of PTFE tubing packed with immobilized antibodies or haptens. The immunoreaction and the chemiluminescence reaction takes place within the immunoreactor, and the emitted light is collected directly from the cell.

As the antibodies are immobilized and the immunoreactor can be used repeatedly, the consumption is minimum; on the other hand, the binding reaction also represents a preconcentration of the sample, and pretreatment is usually not necessary.

A comparison of fluorescent immunoassay and enzyme-multiplied immunoassay techniques (EMITs) concluded that they are similar in terms of accuracy, precision, and simplicity; however, the sensitivity of fluorescent immunoassay is better by a factor of  $\sim 8$  than that of EMITs, but the assay time for fluorescent immunoassay is longer. The comparison was performed on the measurement of serum carbamazepine.

A pH-enzyme optode spectrophotometric flow injection system has been used for monitoring clinical hemodialysis. The role of the incorporated dialyzate urea detector is played by an optical flow-through biosensor based on Prussian Blue film with chemically linked urease forming a monomolecular layer of the enzyme. This pH-enzyme optode-FIA system is useful for selective determination of postdialyzate urea in the range of concentrations corresponding to its level in real clinical samples ( $2\text{--}16\text{ mmol l}^{-1}$ ) at  $\sim 15$  samples of spent dialyzate per hour.

Potentiometric, capacitive, and amperometric transducers have been used for direct and indirect electrochemical immunoassays. However, due to their fast detection, broad linear range, and low detection limit, amperometric transducers are preferred.

Developments in the sensor fabrication techniques coupled to a flow injection assembly have been incorporated in real-time monitoring of biospecific interactions. The assembly utilizes screen-printed

**Table 7** FIA-immunoassays

Detection	Drug (matrix)	Procedure
Chemiluminescence	Digoxin and triiodothyronine (serum)	Acridinium system. Solid-phase reactor in flow cell
	Uric acid (plasma)	Luminol; carbonate buffer at pH 9; uricase and peroxidase on polymer beads in the flow cell
	Rabbit IgG	System sodium tetraphenylborate and <i>p</i> -phenylphenol + luminol/H <sub>2</sub> O/horseradish peroxidase
Fluorescence	Phenytoin (serum)	Competitive binding of fluorescein-labeled and unlabeled phenytoin with a phenytoin antibody; gel filtration
	Atrazine in rabbit anti-atrazine antisera	Protein A/G bonded to an azlactone-activated polymeric support
	4-Nitrophenol	Competitive labeled 4-nitrophenol derivative (tracer) and the analyte
	2,4-Dinitrobenzenesulfonate (DNP)-BSA	Sephacrose. Cation exchange column; fluorescein isothiocyanate-labeled antibody to DNP
	Total disopyramide in serum	Equilibrium dialysis of samples before analysis
	Gentamicin (serum) <sup>a</sup>	Enzyme immunoassay versus a radioimmunoassay
	Carbamazepine (serum) <sup>a</sup>	Fluorescent immunoassay versus EMIT
	Cotinine (saliva and serum) <sup>a</sup>	Monoclonal and polyclonal antibodies versus cotinine in nonisotopic and isotopic immunoassays
Electrochemical	Simultaneous determination of galactose and galactose-1-phosphate in a dried blood disk <sup>a</sup>	Enzyme-immobilized column
	Chorionic gonadotrophin (human blood serum)	Ferrocenecarboxylic acid conjugated with anti-human chorionic gonadotrophin immunoglobulin G antibody. Separation in a capillary column
	IgG	Amperometric detection using antibodies immobilized by physical absorption label, substrate alkaline phosphatase naphthyl phosphate
	4-Nitrophenol	Glucose dehydrogenase amperometry biosensor
	Atrazine	Electrochemiluminescence; atrazine antibodies, atrazine labeled with glucose oxidase
	Cocaine	Online detection of the label alkaline phosphatase by a substrate-recycling biosensor
	Angiotensin	Amperometric quantification of hippuric acid from hippuryl-histidyl-leucine
	<i>Escherichia coli</i> and <i>Salmonella</i>	Porous nylon membranes as a support for anti- <i>Escherichia coli</i> or anti- <i>Salmonella</i> antibodies
	Staphylococcal protein A	Amperometric immunosensor. Anti-protein A antibodies immobilized on dispersed C-powder
	Digoxin	Tyrosinase label – detecting the phenolic product liberated by an alkaline phosphatase

<sup>a</sup>Comparative assays.

electrodes incorporating the electroactive polymer, polyaniline, which brings about mediator-less redox coupling between the electrode and biomolecular components attached to the polymer surface. This system also utilizes enzyme-labeled antibodies as the biomolecular recognition component for the analysis of the test analyte, biotin.

### Introduction

In the last 25 years it has been demonstrated that flow injection analysis (FIA) is a powerful tool for real-time monitoring and control of industrial processes. Its versatility makes possible the setting up of FIA devices for measuring a number of physical, chemical, and biochemical parameters.

Here, we present an overview of the instrumentation and operational modes used in FIA for industrial applications. Different applications of this technique, which can be applied for specific purposes in various industries, are discussed, with particular emphasis on the chemical industry, biotechnology, the food and beverages industry, and wastewater control.

### General Considerations

FIA has many features that make it a valuable technique for industrial analysis and for online process monitoring and control. Most FIA techniques used in the laboratory can be adapted to industrial analysis. Sampling is of utmost importance in industrial analysis since very often the analyzed liquids are not homogeneous. FIA cannot directly improve the

sampling capabilities of an analytical system. Nevertheless, due to the large pool of data that it can provide, greater statistical confidence can be placed in the results obtained.

### Instrumentation and Operational FIA Modes in Industrial Analysis

The instruments used for continuous monitoring and control of industrial plant process must be much more robust than those used in the laboratory. They are intended to work in a nonprotected, often hostile environment, over long periods of time and with no operator present to survey them. Frequently, the industrial samples analyzed contain suspended particles that can easily block the small-bore (0.5 mm inner diameter (ID)) tubes used in the construction of laboratory FIA instruments. This problem can be solved either by inline filtration of samples or by using larger (2 mm ID) tubes. The latter solution is often chosen because frequent change of filters is involved in the former. Polytetrafluoroethylene and stainless steel are used to make the tubes. Gas-driven and peristaltic pumps are the usual pumping systems, the former finding particular use in FIA process monitoring and control. Injection of samples into the FIA devices used in industrial analysis is carried out by means of injection valves similar to those used in low-pressure liquid chromatography, or injection is carried out hydrodynamically. Almost any flow-through detector can be used in FIA devices for industrial analysis.

In the last two decades the major chemical instruments producers have introduced in their product lists

### Introduction

In the last 25 years it has been demonstrated that flow injection analysis (FIA) is a powerful tool for real-time monitoring and control of industrial processes. Its versatility makes possible the setting up of FIA devices for measuring a number of physical, chemical, and biochemical parameters.

Here, we present an overview of the instrumentation and operational modes used in FIA for industrial applications. Different applications of this technique, which can be applied for specific purposes in various industries, are discussed, with particular emphasis on the chemical industry, biotechnology, the food and beverages industry, and wastewater control.

### General Considerations

FIA has many features that make it a valuable technique for industrial analysis and for online process monitoring and control. Most FIA techniques used in the laboratory can be adapted to industrial analysis. Sampling is of utmost importance in industrial analysis since very often the analyzed liquids are not homogeneous. FIA cannot directly improve the

sampling capabilities of an analytical system. Nevertheless, due to the large pool of data that it can provide, greater statistical confidence can be placed in the results obtained.

### Instrumentation and Operational FIA Modes in Industrial Analysis

The instruments used for continuous monitoring and control of industrial plant process must be much more robust than those used in the laboratory. They are intended to work in a nonprotected, often hostile environment, over long periods of time and with no operator present to survey them. Frequently, the industrial samples analyzed contain suspended particles that can easily block the small-bore (0.5 mm inner diameter (ID)) tubes used in the construction of laboratory FIA instruments. This problem can be solved either by inline filtration of samples or by using larger (2 mm ID) tubes. The latter solution is often chosen because frequent change of filters is involved in the former. Polytetrafluoroethylene and stainless steel are used to make the tubes. Gas-driven and peristaltic pumps are the usual pumping systems, the former finding particular use in FIA process monitoring and control. Injection of samples into the FIA devices used in industrial analysis is carried out by means of injection valves similar to those used in low-pressure liquid chromatography, or injection is carried out hydrodynamically. Almost any flow-through detector can be used in FIA devices for industrial analysis.

In the last two decades the major chemical instruments producers have introduced in their product lists

FIA analyzers or FIA components. One company produces a series of instruments that are flow injection systems with atomic absorption spectrometric detection dedicated to determination of mercury. Some companies produce flow injection analyzers for a large number of ions. One supplier has an analyzer that comprises three separate units: a basic analytical module, an automatic sample module, and a data capture module, all these units being completely automated. The instrument is capable of analyzing nutrients, ions, and metals. It offers a wide analytical choice using ion-selective electrodes (ISEs), chemiluminescence, or fluorescence. With analysis speeds up to 120 samples per hour and detection limits down to parts per billion levels, this flow injection analyzer performs determinations well compared with other techniques.

The FIA techniques used in industrial analysis are mostly based on modification of the chemical matrix of the sample to be analyzed. This modification can be achieved by passing the analyte into another medium, by dilution, or by matrix matching. Transfer of the analyte into a different medium is the method most commonly used for modifying the sample matrix, the purpose of the modification being to increase the selectivity and, in some cases, the sensitivity of the method. It can be carried out by solvent extraction, gas diffusion through membranes, dialysis, etc. Sample dilution, which is often necessary in industrial analysis, is usually done by sample splitting and zone sampling. Matrix matching is required when certain types of detector are used. The parameters that depend on the chemical matrix of samples and which must be considered include the ionic strength, refractive index, pH value, viscosity, etc. For FIA control of some biotechnological process, inline conversion techniques based on enzymatic microreactors are used.

Two operational FIA modes are used for analyzing industrial samples, particularly for continuous process monitoring and control. In the first mode, which is the basic FIA technique, the sample to be analyzed is continually drawn out from the process to be monitored and periodically injected into the carrier stream and thus into the FIA channel. The system is first calibrated using one or several standards of known concentration; the process is then monitored via periodic sampling. The instrument may be rechecked by injecting another series of standards. In the second operational mode it is the reactant that is injected. The sample solution is pumped continuously through the FIA system and the reactant, which generates the product whose property is measured, is injected into this stream at predetermined time intervals. This technique, known as reversed FIA, has the

advantage of conserving the reagent. It has, however, the disadvantage that the detector may eventually become fouled due to a lack of carrier stream, and, moreover, the amount of sample needed is relatively large.

### **Advantages of Applying FIA to Industrial Analysis**

Among the advantages of using FIA in industrial analysis are the following: rapid changes of methods are possible, the throughput is large, the data are acquired in real time, and there is the possibility of performing matrix modification. Real-time or near-real time acquisition of data is critical to the efficiency of a process control system. Normally the process stream has a matrix, which makes it difficult to measure the analyte, and hence matrix modification is necessary in order to develop industrial analytical methods. Pretreatment (matrix modification) and analysis, including chemical conversion, can be carried out very rapidly. The entire operation usually takes less than 1 min.

The FIA system can be used to automate existing methods or to introduce minor modifications and improvements. Thus, the FIA system can utilize selectivity enhancement, kinetic discrimination, and matrix optimization to create new methods that are not applicable to batch or segmented continuous-flow systems. Reproducibility is excellent, partly due to the elimination of human intervention and bias. The FIA system is closed, making it suitable for use with volatile or toxic substances, and offers the advantage of removing, or at least minimizing, human exposure. The equipment is simple, rugged, and inexpensive. The hardware is computer compatible, and therefore the analyses can be automated easily. Calibration is also easy, baseline conditions are continuously monitored, and the detector is continuously cleaned by the carrier. High pressures and temperatures can be used.

### **Industrial Processes**

Process monitoring and control is one of the chief fields of interest in modern analytical chemistry. In spite of the advantage to be gained by using FIA for online process monitoring and control, the number of applications proposed so far is very low, given the technique's potential. Until the mid-1980s hardly any reference could be found to the industrial application of FIA for real process monitoring. This was at least partly due to problems associated with the design and construction of adequate sampling and sample conditioning systems. The use of membranes for dialysis, gas diffusion, and other separative and

preconcentration techniques merits more attention for online process analysis. Several novel process FIA instruments have come into the market in the past few years, and other companies working in this area expected to introduce systems in the near future. In some cases the interested companies have built their own FIA instruments devoted to process monitoring. Many FIA process control applications have not yet been published, to avoid divulging proprietary data.

The FIA analyzers available for online process monitoring are sturdy and have been field tested, with proven design of components. The functional parameters, as well as the data acquisition and reporting functions, are microprocessor controlled. These analyzers still preserve all the FIA advantages, they are easy to service, and the systems can be safely placed in corrosive or hazardous environments. One company, for instance, produced FIA instruments designed specifically for online process monitoring and control of industrial plant processes with the features mentioned above. These instruments are designed to reside at the process line and can accommodate a high-pressure sample line. Several other firms produce FIA instruments that are able to analyze industrial samples with complex composition. These devices were originally designed to work under laboratory conditions but can be adapted easily to process monitoring and control. **Figure 1** shows an FIA device for online process monitoring with automatic calibration that can also be utilized for analyzing separate samples. Often these types of analyzer are modular. The modules can be combined in a variety of ways, and switching between analytical methods is simple. The analyzers can be equipped with a wide variety of detectors, gas-sensitive electrodes, etc. Using interchangeable analyzers, the time between individual analyses can be set at an optimal value in order to allow both accurate control of the process and a saving of the reagents. The

calibration can be programmed to be carried out as frequently as necessary.

By making use of FIA process monitoring and control, the measured parameters can be maintained at the desired optimal values. This leads to an increase in the quality of the products obtained and also to significant savings by allowing a decrease in the number of personnel required and reducing expenditure on materials and energy. Some important examples of application of FIA to online process monitoring and control are listed in **Table 1**.

## Biotechnological Processes

The need for better monitoring and control of bioreactors has become greater as more and more processes are studied. The control and optimization of fermentation requires online information about the biological processes involved. Thus the concentrations of the various biological factors the substrate, some enzymes, some ions, and the product must all be determined in order to provide precise feedback for better control. Conventionally, most industrial biotechnological processes are determined offline in the laboratory, after withdrawal of separate samples. This method, however, is not satisfactory due to the time delay, the limited reliability, and the manpower needed for analysis of a large number of samples. Inline sensors appear to be the ideal choice, but although their use is increasing, they show some reliability problems. For this reason, analytical approaches based on continuous sampling, followed by automatic online analysis, are currently being used. The traditional automatic analyzers used for this purpose are increasingly being supplanted by FIA devices. The FIA systems offer fast, selective analysis on request, based on classical wet chemistry, and allow integration of automated sterile sample taking

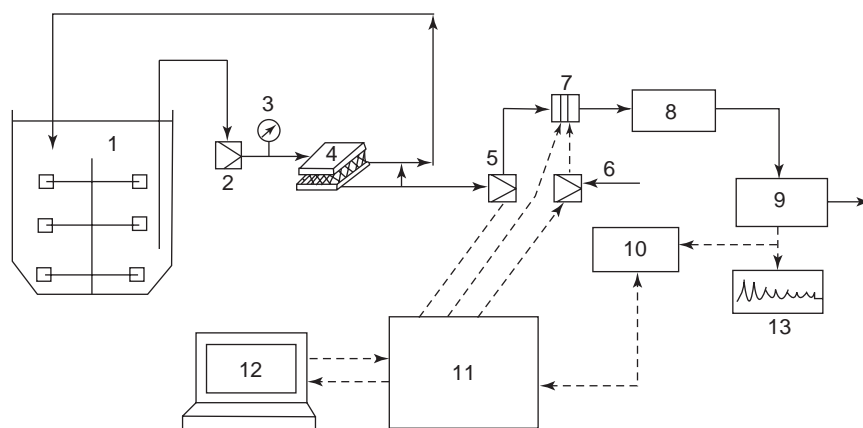

**Figure 1** A single-line FIA analyzer for online process monitoring with automatic calibration. Inset: The shape of the output signal from the analyzer.

**Table 1** Features of FIA online process monitoring and control

Analyzed species	Measuring range	Type of sample	Detection
Sodium hydroxide	0–4 g l <sup>-1</sup>	Caustic process stream	Potentiometry
Sodium carbonate	0–7 g l <sup>-1</sup>	Potentiometry	Potentiometry
Hydrochloric acid	9–38% (m/m)	Concentrated HCl production plants	ISE
PH	4.5–9.5	Water in power plant cycles	pH electrode
Ammonia	0.2–3 mg of N per liter	Water in power plant cycles	Spectrophotometry
Hydrazine	0.025–0.3 mg l <sup>-1</sup>	Water in power plant cycles	Spectrophotometry
Fe	0.01–10 mg l <sup>-1</sup>	Water in power plant cycles	Spectrophotometry
Cu	0.02–0.2 mg l <sup>-1</sup>	Water in power plant cycles	Spectrophotometry
Zn	0.2–60 g l <sup>-1</sup>	Process stream in hydrometallurgical plants	Spectrophotometry
Zn	mg l <sup>-1</sup> up to 110 g l <sup>-1</sup>	Galvanizing preflux solutions	Atomic absorption spectrometry
Ti	2.5–30 mg l <sup>-1</sup>	Brine	Spectrophotometry
Fe(III)	0.5–180 mg l <sup>-1</sup>	Mineral process liquors	Spectrophotometry
Fe(II)	0.5–120 mg l <sup>-1</sup>	Mineral process liquors	Spectrophotometry
Ni(II)	0.17–0.24 mg l <sup>-1</sup>	Electroplating bath	Spectrophotometry
NH <sub>3</sub>	70–2000 mg l <sup>-1</sup>	Organic solvents	Spectrophotometry
Peroxide (active oxygen)	0–1000 mg l <sup>-1</sup>	Organic process streams	Spectrophotometry
Sulfuric acid	20–100 mg l <sup>-1</sup>	Phenol/acetone matrix	Conductimetry
Free fatty acids	0.01–0.3% (m/m)	Edible oils	Spectrophotometry
Hg	0.1–100 µg l <sup>-1</sup>	Zinc battery anode	Atomic fluorescence spectrometry
Cu	0.2–1.0 mg l <sup>-1</sup>	Effluent streams	Spectrophotometry
Carbonyl	0.05–1.0 carbonyl number	Organic intermediates	Spectrophotometry
Water	0.001–0.1% (m/m)	Organic solvents	Spectrophotometry
Cyanides	0.1–1.0 mg l <sup>-1</sup>	Industrial effluents	Spectrophotometry
	20–1000 mg l <sup>-1</sup>	Process solutions	ISE
Sulfate	0.05–0.5 g l <sup>-1</sup>	Basic solutions	Spectrophotometry

and preparation during analysis. The combination of suitable sampling devices with FIA systems is the prerequisite for online control of bioreactor processes. By using an FIA manifold such as that illustrated

in **Figure 2**, a system can be constructed that, in addition to having a high sampling frequency, offers the benefit of real-time continuous monitoring by aspirating the sample solution regularly (e.g., from a

batch-type bioreactor) into a carrier/wash solution. The signals, recorded as a series of peaks (the injected samples superposed upon a constant background of the carrier/wash solution), can provide positive control of both the detector and the process. Fouling of the detector is prevented by the periodic wash sequence of the carrier stream. Injection of calibration samples from time to time allows an additional control for correct functioning of the detector.

Different FIA procedures have been developed for biotechnology applications, especially for online glucose analysis. Some methods use continuous enzymatic reagent consumption, and some use enzyme immobilization techniques. The former are more versatile, easier to assemble, and more robust. The latter are simpler and more economical, but due to the nature of enzyme kinetics, it is difficult to measure substrate concentrations above  $1\text{ g l}^{-1}$  without the use of dilution techniques, which may affect the final result.

The measurement of enzyme activity has been used as a direct control parameter for achieving optimal fermentation. At present, the most common enzymes are determined offline in the laboratory, after withdrawal of a separate sample. With FIA it should be easy to develop automatically operated enzyme determination procedures, based on reaction schemes, that can be used for fast and efficient process monitoring and control. For instance, the feasibility of online measurement during the fermentation of extracellular hydrolases (proteases or glucosidases) on a 30 or 70 l pilot scale has been demonstrated. The changes in the concentrations of the solutes caused by the enzyme activity were monitored spectrometrically. An FIA system devoted to online monitoring of formate dehydrogenase and leucine dehydrogenase in the control of enzyme production process has also been proposed. An online FIA system has also been developed for intracellular ATP measurement in a culture fluid of yeast and *Escherichia coli*; it uses a luminescent reaction for determination of the microorganism cell number.

A flow injection immunoanalysis system connected via a sterile sampling unit to a continuous bioreactor has been used for online monitoring of monoclonal antibodies in the course of a hybridoma cell fermentation. Mouse IgG and rabbit antimouse IgG immobilized in a macroporous network have been used for an antigen inhibition assay and sandwich assay, respectively. The product of the enzymatic indicator was measured fluorimetrically.

There are many applications of FIA in the control of biotechnological processes, some of which are listed in Table 2.

## Food and Beverage Industry

FIA affords a means of automating many traditional wet-chemical methods of food and beverage analysis, incorporating into them the rapid throughput and high reproducibility that characterize FIA methods. Analysis using standard or official chemistries may be achieved in a very short time (typically 30 s).

For example, Figure 3 shows an automated FIA system used for quality control of olive oil through the use of a distributed expert system. This system consists of four nodes: node 1 controls pump 1 and the spectrophotometer and connects the system to the PC; node 2 measures the total acidity; node 3 measures the peroxide; and node 4 is responsible for ultraviolet spectrophotometric measurements.

The use of FIA with immobilized enzymes combines the advantage of enzymatic analysis with the rapidity and versatility of flow techniques. Numerous methods have been based on this combination of techniques, and the number of applications in food and beverage analysis is increasing. Approximately 30% of the proposed methods use enzymes, 99% of which are immobilized. Very good results have been obtained by combining the specificity of the enzymatic reactions with the high sensitivity of chemiluminescent detection. Many oxidases react with their substrates to produce hydrogen peroxide, which can be quantified by chemiluminescence. Chemiluminescent (CL) monoenzyme sensors based on optical fibers have been developed for FIA determination of hydrogen peroxide, xanthine, and hypoxanthine using microbial peroxidase or xanthine oxidase. To develop bienzyme sensors for glutamate, lysine, and xanthine the microbial peroxidase was coimmobilized with the corresponding oxidases. FIA systems with CL detection and minicolumns with immobilized glucose oxidase, alcohol oxidase, cholesterol oxidase, glutamate oxidase, and lysine oxidase for glucose, ethanol, cholesterol, glutamate, and amino acid determination in foodstuffs and beverages show extremely promising features.

The lack of ready-made FIA methods of food and beverage analysis in the literature should not be a discouragement since it is relatively easy to adapt an existing classical method to FIA. All that is required is the empirical selection of manifold designs and reagent concentrations to produce outputs of suitable magnitude over the working range. On the negative side, the total analysis time for foods will be dictated by the need for sample extraction and possibly clean-up prior to FIA, but this need not to be a serious drawback and is equally applicable to other techniques.

**Table 2** FIA applications in the control of some biotechnological processes

Analyzed species	Detection <sup>a</sup>	Linear range	Sample
Total glucose	Amperometry	10–600 $\mu\text{mol l}^{-1}$	Fermentation process
Intracellular ATP	Chemiluminescence	0.01–1.0 $\text{mmol l}^{-1}$	Kefir fermentation
Glucose	Chemiluminescence	10 $\text{mg l}^{-1}$ –2 $\text{g l}^{-1}$	Lactic acid fermentation
Glucose	Spectrophotometry	500 $\text{mg l}^{-1}$ –3 $\text{g l}^{-1}$	Mammalian cell culture
Glucose	Amperometry	2–100 $\text{g l}^{-1}$	Fermentation broth
Fructose	Thermistor	0.1–0.75 $\mu\text{g ml}^{-1}$	Fermentation broth
Sucrose	Amperometry	0–2.5 $\text{g l}^{-1}$	Effluents from pharmaceutical industry
Ammonia	Spectrophotometry	0.1–2 $\text{mmol l}^{-1}$	Hybridoma cell culture
Glutamine	Spectrophotometry	0.07–2 $\text{mmol l}^{-1}$	Hybridoma cell culture
Glutamine	Chemiluminescence	0.001–1 $\text{mmol l}^{-1}$	Animal cell culture
Glutamate	Chemiluminescence	0.0001–1 $\text{mmol l}^{-1}$	Animal cell culture
L-Methionine	Thermistor	10–60 $\text{mmol l}^{-1}$	Fermentation broth
IgG	Fluorimetry	5–500 $\mu\text{g ml}^{-1}$	Mammalian cell culture
Lactic acid	Fiber optic biosensor	0–50 $\text{mmol l}^{-1}$	Lactic acid fermentation
Lactic acid	Chemiluminescence	0.1–2 $\text{g l}^{-1}$	Lactic acid fermentation
L-Lactate	Amperometry	1–60 $\text{g l}^{-1}$	Effluents from pharmaceutical industry
Extracellular proteins	Spectrophotometry	0.1–2 $\text{g l}^{-1}$	<i>Trichoderma</i> fermentation
L-Phenylalanine	Fluorimetry	0.1–1.2 $\text{mmol l}^{-1}$ , 1–30 $\text{mmol l}^{-1}$	<i>Rhodococcus</i> cultivation
Optical density	Spectrophotometry	< 200 $\text{mg l}^{-1}$	Biotechnological process
Extracellular hydrolases	Spectrophotometry	50–500 $\text{U ml}^{-1}$	Fermentation broth
Intracellular $\beta$ -Galactosidase activity	Spectrophotometry	50–5100 $\text{U ml}^{-1}$	<i>Escherichia coli</i> fermentation
Lipase activity	Spectrophotometry	0.6–5 $\text{U ml}^{-1}$	<i>Candida rugosa</i> fermentation
$\beta$ -Galactosidase activity	Spectrophotometry	25–2150 $\text{U ml}^{-1}$	<i>Escherichia coli</i> culture
Formate dehydrogenase activity	Spectrophotometry	0.05–20 $\text{U ml}^{-1}$	<i>Candida beldinii</i> culture
Esterase activity	Spectrophotometry	0.01–1.0 $\text{U ml}^{-1}$	Fermentation broth

Table 3 presents details of several FIA methods, together with some of their features, that have already been applied to the analysis of foods and beverages.

Beverages were the first area of application of FIA in the beverage and food industry since being liquids they require little or no sample preparation prior to analysis. The analysis of soft drinks for quality control purposes normally includes the determination of pH, sugars, acidity, preservatives, and trace metals (e.g., lead and cadmium); moreover, colas are also analyzed for caffeine, and soda water for hydrogen-carbonate. FIA may be utilized to carry out many of these determinations. FIA has also been employed for determinations more specific to beer, wine, and milk. FIA titration has been used to determine volatile acids in spoiled beer samples. Bitterness in beer is determined by solvent extraction from an acidified carrier stream and measurement of the absorbance of the solvent stream at 275 nm. The reducing sugars in wine have been determined by automation of classical colorimetric reactions using FIA.

A number of FIA applications are made possible by the fluorimetric determination of nicotinamide adenine dinucleotide in its reduced form at 365 nm (excitation) and 400 nm (emission). This way ethanol in wine and pyruvate in milk can be determined.

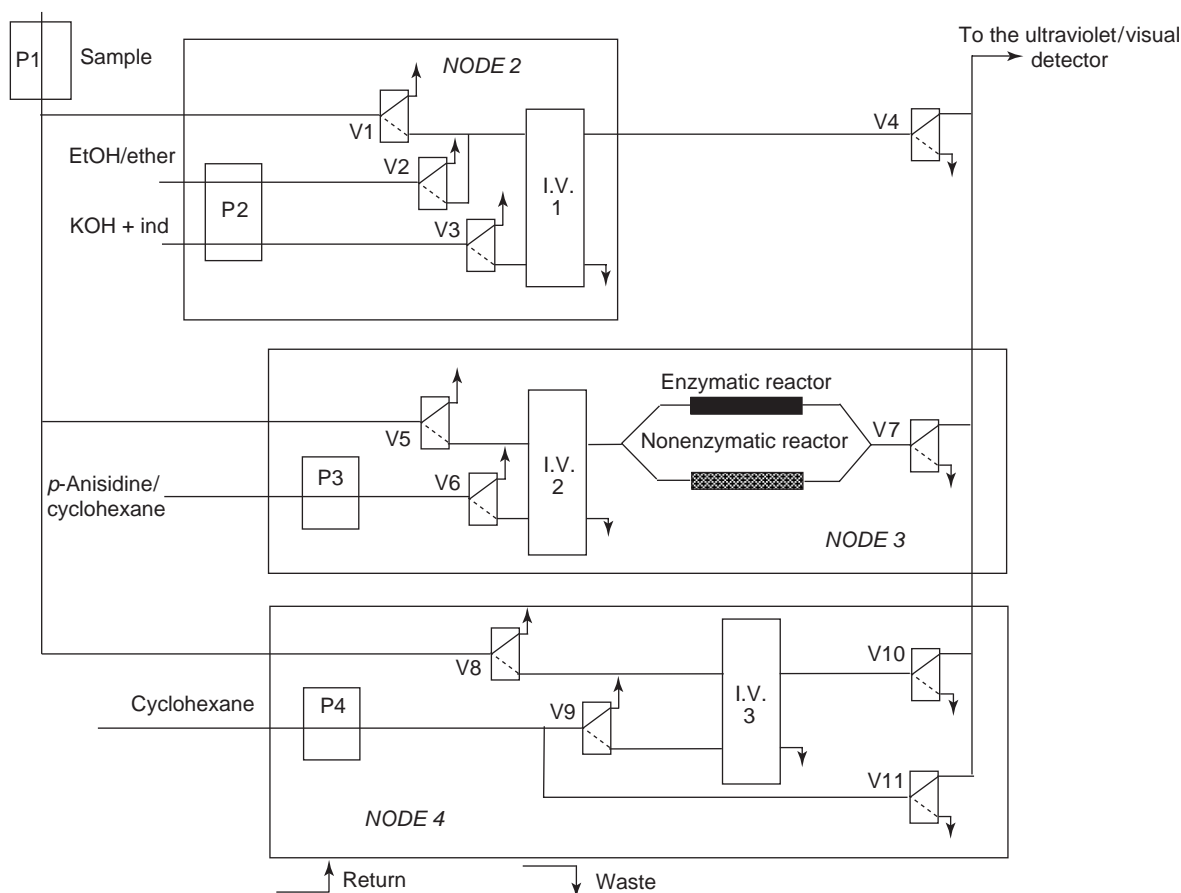

Table 3 gives some examples of FIA determinations in beverage and food samples in this context.

FIA offers a means of carrying out beverage and food analysis based on classical chemistry that is simple, precise, and quick. Rapid development of a method is possible, and changeover from one determination to another is quick and easy.

## Wastewater Monitoring

Nowadays, control and treatment of industrial effluents has become one of the most important steps of productive processes since the regulatory laws have been very rigorous about environment protection. As a consequence, automated, robust, and multiparametric methods capable of reducing drastically both the reagent consumption and the analyst manipulation together with the feasibility of achieving a high sample throughput need to be designed.

Although originally flow injection techniques were developed for off-site measurements, their outstanding feature is the capability for both *in situ* and real-time monitoring of chemical parameters in water. This way, the simultaneous determination of the relevant parameters in water samples such as ammonium, nitrite, nitrate, total nitrogen, orthophosphate, total phosphate, and total organic carbon is possible (Table 4).

**Figure 3** Configuration of a distributed FIA system for quality control of olive oil. Ind, indicator (phenolphthalein); P, peristaltic pump; I.V., injection valve; V, electrovalve. (Reproduced with permission from Bonastre A, Ors R, and Peris M (2004) Advanced automation of a flow injection analysis system for quality control of olive oil through the use of a distributed expert system. *Analytica Chimica Acta* 506: 189–195.)

Different miniaturized flow injection analyzers have been constructed using spectrophotometry as a leading detection technique. Besides, electrochemical techniques such as amperometry and potentiometry with chemically modified solidstate electrodes and tubular membrane-based ISEs, respectively, have been proved to be well adapted to multiparametric measurements of inorganic species present in wastewater, using multiple sensor arrays.

The advantage of the FIA technique lies in the possibility of implementing heterogeneous reactions, dilution procedures, or separation steps using inline gas-permeable and dialysis units.

Phenolic compounds and especially their chlorinated derivatives are important water pollutants that are present in wastewater discharged from a variety of industrial sources. A fast method for direct determination of phenols in wastewater based on solid-phase extraction coupled online to a flow injection manifold has been developed. The phenol

preconcentration is carried out in a column packed with Amberlite XAD-4 resin and inserted in the FIA manifold. The eluted phenols are spectrophotometrically determined as products of reaction with 4-aminoantipyrine and potassium ferricyanide.

A rapid flow injection analyzer for successive determination of ammonia, nitrite, and nitrate in water using gas-phase chemiluminescence has been used with good results for water quality control in sewage plants and water purification plants.

A low-cost and robust FIA method for total phosphorus in wastewater is based on a two-stage photooxidation/thermal digestion procedure together with a mixed oxidizing/hydrolyzing reagent for converting phosphorus compounds to orthophosphate. The formed orthophosphate is then determined by the phosphomolybdenum blue reaction.

One company has installed complete water monitoring stations based on the flow injection principle with colorimetric, fluorimetric, and ISE detection, and these have been functioning for many years now.

**Table 3** Features of FIA determinations in beverage and food samples

Analyzed species	Measuring range	Type of sample	Detection
Glucose	0.01–3 mmol l <sup>-1</sup>	Foodstuffs	Amperometric biosensor
Sucrose	0.04–2 mmol l <sup>-1</sup>	Soft drinks	Chemiluminescence
Sucrose	11–14% (m/m)	Sugarcane	Spectrophotometry
Glucose	0.2–1.0 mmol l <sup>-1</sup>	Soft drinks	Spectrophotometry
Fructose	0.02–2 mmol l <sup>-1</sup>	Common fruits	Amperometry
Lactose	0.1–1.5 mmol l <sup>-1</sup>	Milk	Spectrophotometry
Lactose	25–250 mmol l <sup>-1</sup>	Milk	Amperometry
Raffinose	0.5–6 mmol l <sup>-1</sup>	Foodstuffs	Amperometry
Glucose	0.001–0.01 mmol l <sup>-1</sup>	Fruit juice	Fluorimetry
Starch	0.1–1000 mg l <sup>-1</sup>	Potatoes	Amperometry
Ethanol	6–12% (m/m)	Wine, spirits	Enthalpimetry
Ethanol	0.002–0.016%	Wine	Photodiode array
Glycerol	2200 mmol l <sup>-1</sup>	Wine	Amperometry
Acetaldehyde	0.5–11 mg l <sup>-1</sup>	Wines	Spectrophotometry
SO <sub>2</sub> , free total	1–16 mg l <sup>-1</sup>	Wines	Spectrophotometry
Sulfite	1–10 mg l <sup>-1</sup>	Juices, vegetables	Spectrophotometry
Tartaric acid	0.02–4 g l <sup>-1</sup>	Wines	Spectrophotometry
Glutamic acid	0.01–0.5 mmol l <sup>-1</sup>	Cheese	Fluorimetry
Ascorbic acid	0.140 mg l <sup>-1</sup>	Fruit juice, jam	Spectrophotometry
L-Lactate	20–650 mg l <sup>-1</sup>	Milk, foodstuffs	Spectrophotometry

## Overview

**M E Díaz-García and R Badía-Laiño**, University of Oviedo, Oviedo, Spain

## Introduction

Molecular photoluminescence processes can be classified according to the mode in which a molecule is promoted to an electronically excited state and to the type of molecular excited state (see **Table 1**). As the excited molecule decays back to the ground state, or to a lower-lying excited electronic state, light is

emitted at a characteristic wavelength. All the processes that involve the emission of electromagnetic radiation are called luminescence.

Following absorption, a number of vibrational levels of the excited state are populated. Molecules in these higher vibrational levels then decay to the lowest vibrational level of the excited state (vibrational relaxation). Fluorescence is the radiation released when a molecule, which has been promoted to an excited singlet state by light absorption, rapidly relaxes from the lowest vibrational mode of the electronically excited state  $S_1$  (Kasha's rule) to a vibrational mode of the electronic ground state  $S_0$ . The energy transitions associated with photoluminescence can be represented on Morse energy surface diagrams (Figure 1). In addition to fluorescence, the energy of the excited state may be dissipated by

nonradiative decay processes, such as fluorescence energy transfer, collisional quenching, or intersystem crossing.

Fluorescence spectrometry has become established as a routine technique in many specialized applications due to its high sensitivity. Examples of the current applications of fluorescence range from simple fluorimetric analysis for biomolecules, metal ions, and organic compounds to identification of specific DNA and/or RNA sequences in tissues. In addition, much of the current research in biochemistry, medicine, and molecular biology involves fluorescence spectroscopy of either intrinsic molecular fluorescence (from tyrosine or tryptophan residues) or exogenous fluorescent probes.

Besides high sensitivity, fluorescence exhibits unique performance characteristics among which selectivity, reproducibility, and temporal resolution are included. It is relatively a simple and rapid analytical technique, specially adequate for quantification of aromatic, or highly unsaturated, organic molecules present at trace concentrations, especially in biological and environmental samples. The technique can also be applied to a wide variety of organic and inorganic compounds via chemical labeling and derivatization procedures and can be used as the detection mode in flow injection analysis, chromatography, capillary electrophoresis, and thin-layer chromatography. Fluorescence output is linear to sample concentration over a very broad range and the technique can be used over three to six decades of concentration without sample dilution or modification of the sample cell. On the other hand, almost any liquid, gaseous, or solid sample can be analyzed by fluorescence. Sample size can be extremely small and nanoliter sample volumes may be analyzed using

specialized techniques. Even, using sophisticated techniques (e.g., flow and image cytometry), single molecules can be studied via fluorescence, while multiple targets can be detected during a single assay by using a combination of fluorophores.

Fluorescent dyes and tailor-made fluorescence-labeled compounds are growing commercially for coupling not only to metal ions but also to biomolecules, as a result of the increasing demand for identification of molecular interactions and for the visualization, recognition, and quantification of molecules, which bind to target molecules like peptides, proteins, nucleic acids, carbohydrates, etc. Companies have built the basic chemistries into user-friendly kits and systems that make labeling easy. Fluorescence spectroscopy has evolved to a routinely used ultra-sensitive detection technology on high-throughput screening, from a 96-well situation up to high-density 384- and 1536-well platforms. An integration of combinatorial chemistry and fluorescence spectroscopy creates a powerful tool to probe biological targets. A consistent theme of fluorescent technologies is their adaptability to users' needs in both industry and academe.

## Basic Instrumentation for Molecular Fluorescence Measurement

A block diagram of a basic fluorimeter is shown in Figure 2. Aside from the optical components shown, modern fluorimeters have dedicated computers, which may control instrumental operating parameters, the acquisition of spectral data and the post-processing of the data.

**Figure 2** Basic component of a spectrofluorimeter.

## Sources

The source used in most commercial fluorimeters is the 75–450 W xenon arc lamp, which covers the range of 200–1000 nm. However, for greater excitation energy at selected wavelengths, the mercury-arc lamp may be used, although excitation spectra obtained with this lamp are usually severely distorted because principal lines (at 254, 302, 313, 546, 587, 691, and 773 nm) are superimposed on a continuum. Lasers are now increasingly used due to the high optical power (number of photons per unit time). A few fluorescence instruments using laser sources are commercially available and most are intended for specific applications such as analyses of uranium in the nuclear industry and for remote measurements using optical fibers. In some applications, such as frequency domain lifetime measurements, it may be necessary to modulate the intensity of the source. In these cases, some classes of laser or light-emitting diodes are suitable sources.

## Wavelength Selection

Isolation of selected wavelengths is carried out with filters, usually in conjunction with white light sources. Filters are used in inexpensive, portable fluorescence spectrometers and their optical quality will often determine the performance of the instrument. Filters allow transmission of a very large number of photons from the source to the sample and from the sample to the detector (fluorescence signal is maximized) but have poor wavelength selectivity. While filters can be used for limited applications, grating monochromators are used in most spectrofluorimeters. For optically clear solutions, single-grating monochromators are adequate while double-grating monochromators are ideal for turbid solutions as stray light and scattering is reduced. The emission wavelength selector system is generally placed at an angle of 90° with respect to the excitation axis to minimize interferences from transmitted and scattered exciting light.

## Sample Illumination

The most common arrangement uses the 90° geometry depicted in Figure 2 rather than the 180° geometry common to absorption spectrophotometers. This geometry is suitable for weakly absorbing solution or diluted samples. For solids (samples adsorbed on solid surfaces such as polymers, paper, etc.) and for solutions that absorb strongly at the excitation wavelength, a front surface geometry is preferable (see Figure 3). Fluorescence is viewed in these cases from the face of the sample on which the exciting light impinges. In the front-face arrangement there is

**Figure 3** Sample geometry and typical cell for fluorescence measurements.

a risk that reflected light from the surface enters the emission monochromator resulting in large amount of stray light. If the solid sample is transparent, back-face illumination is also possible.

In practice, most fluorescence measurements are taken in solution and 1 cm glass or fused silica cuvettes with four polished windows are used. For some specialized applications different types of cuvettes are commercially available. For example, flow cells of different configurations for continuous flow spectrofluorimetric analysis have been designed.

### Detectors

The final basic component of the fluorimeter is the detector, which is placed at the exit slit of the emission-wavelength selection system. A key requirement for a detector is its ability to detect very low radiation levels. Photomultiplier tubes (PMTs) are most widely used because of their high sensitivity. In many cases, PMTs are operated at low temperature to minimize dark counts and to push detection limits lower. The essential principle of the PMT has remained unchanged for many years and its main limitation is that it is a single-channel detector and some important analytical information may be lost when obtaining a spectrum (e.g., in chromatographic applications). An array of detectors, as in many UV-Vis absorption spectrometers, would allow rapid acquisition of full fluorescence spectra. Until now the PMT-based devices remain the most common detectors although new classes of electronic array detectors are beginning to be employed in some fluorimeters. At present, one of the most promising electronic array detectors for fluorimetry is the charge-coupled device (CCD), which essentially is an array of semiconductor photodetectors.

### Information from Fluorescence Measurements

All fluorescent molecules can be characterized by two types of spectra – the excitation spectrum and the emission spectrum. The excitation spectrum is a plot of emitted fluorescence as a function of the excitation wavelength at a fixed emission wavelength. The excitation spectrum represents the relative probability that a fluorescent molecule will be excited by a given wavelength of incident light. If the excitation energy is constant, the fluorescence excitation spectrum is very similar to the absorption spectrum. The photon energy at the maximum of the excitation peak equals the energy difference between the ground state ( $S_0$ ) and a favored vibrational level of the first excited state ( $S_1$ ) of the molecule. In some cases, the excitation spectrum shows a second peak at a shorter wavelength (higher energy) that indicates transition of the molecule from the ground state to the second excited state ( $S_2$ ) (Figure 4).

A plot of the relative intensity of emitted light as a function of the emission wavelength at a fixed excitation wavelength is termed fluorescence emission spectrum. The fluorescence emission is characterized by the transition from the lowest vibrational mode of the electronically excited state ( $S_1$ ) to the ground state. Therefore, the shape of the emission spectrum is always the same and is independent of the wavelength of the exciting radiation.

The shape of the emission spectrum is approximately a mirror image of the longest-wavelength excitation band. Peaks in a fluorescence excitation spectrum usually correspond closely in wavelength to absorption peaks. In theory, the maximum of the emission peak should occur at the same wavelength than that of the excitation peak (commonly called the O–O transition of absorption and emission). In practice, the emission spectrum is always shifted toward a longer wavelength relative to the excitation spectrum, as shown in Figure 4. This difference between the excitation and emission maxima is termed the Stokes shift. The Stokes shift represents the energy lost whilst the molecule was in the excited state and, from a practical point of view, it allows the excitation and emission peaks to be spectrally separated and easily distinguished. When the spectra are scanned, ‘scattering peaks’ usually appear when the wavelengths of excitation and emission monochromators coincide. They can be eliminated if the excitation and emission band passes do not overlap.

The absorption spectrum is reproducible when scanned on different instruments (provided there are no distortions due to inappropriate settings of scan speed, band pass width, source output, etc.).

**Figure 4** Typical features of fluorescence spectra.

However, fluorescence spectra (excitation and emission) are less reproducible because fluorescence spectra are affected by intensity of light source and by the response of photomultiplier detector, both of which vary with the wavelength. Thus, excitation and fluorescence spectra, obtained in the usual nonratio mode with single-beam instruments, are often distorted and not reproducible from instrument to instrument. It is possible to eliminate these variations instrumentally and several commercial instruments are available that provide 'corrected spectra'. These adjust for variations in the source intensity with wavelength and also correct for variations of the detector response.

The emission wavelength and the fluorescence intensity are determined by the structure of the molecule. In principle, any molecule that absorbs radiation of adequate energy could fluoresce. However, many molecules exhibit very weak fluorescence and only a small fraction of molecules exhibit analytically useful fluorescence. Most intensely fluorescent molecules contain highly conjugated  $\pi$ -electron systems. For example, polycyclic compounds such as aromatic hydrocarbons, vitamin K, barbiturates, nucleosides, and conjugated polyenes such as vitamin A are fluorescent. Typically, more the number of conjugated bonds in the molecule, longer is the wavelength of emission observed. The presence of heteroatoms such as O, S, and N, results in  $n \rightarrow \pi^*$  transitions that may promote a change in the spin of the excited electron (intersystem crossing process) and no fluorescence is observed (e.g., pyridine, pyrrole, furan, and thiophene are not fluorescent). Molecules with fused aromatic rings have high molar absorptivity values and, consequently, are highly fluorescent (e.g., naphthalene, pyrene, anthracene). The

presence of heteroatoms in such systems can either decrease or increase fluorescence intensity, depending on the probability of intersystem crossing. Molecules in which it is possible to stabilize charge by resonance are much more fluorescent than those with no resonance structures. A typical example of this is aniline, which is highly fluorescent while anilinium ions are not fluorescent. Finally, more rigid molecules exhibit stronger fluorescence owing to the lower probability of energy dissipation by nonradiative processes such as energy transfer or by transitions between electronic states. So, while biphenyl is weakly fluorescent, fluorene is strongly fluorescent (quantum yield of 1.0). The applicability of fluorescence may be extended to nonfluorescent compounds by converting them to a fluorescent derivative. For example, nonfluorescent steroids may be converted to fluorescent phenolic compounds by dehydration with concentrated sulfuric acid. Antibodies may be made to fluoresce by attaching to it a fluorescent tag or label (e.g., fluorescein isocyanate). Concerning inorganic species, relatively few inorganic metal ions (e.g.,  $\text{UO}_2^{2+}$ , Ce(III), Tl(I)) exhibit intense fluorescence. Nonfluorescent inorganic metal ions may be reacted with aromatic organic ligands to form fluorescent chelates. Considerations about rigidity, conjugated bonds, and aromatic fused rings also apply in these cases.

## Molecular Fluorescence: Practical Considerations

Conventional fluorimetric determinations are carried out in solution with external standardization. When

the native fluorescence of the analyte is measured, minimal sample treatment is necessary and a fluorimetric analysis can be carried out in less than 10 min. However, when fluorimetric derivatization reactions are necessary, the analytical reaction is allowed to reach equilibrium before the fluorescence signal is measured. In any case, the fluorescence signal is related to the analyte concentration.

Solution conditions, such as pH, viscosity, ionic strength, solvents, and reagent concentrations must be carefully adjusted and controlled in order to maximize the fluorescence signal. Background fluorescence from sample matrix or contaminants in solvents, reagents, and/or laboratory glassware can occur over the same wavelength range as the analyte fluorescence (additive interference). This can be a major limitation in achieving optimal detection limits, especially in biological and environmental samples. Background fluorescence can be circumvented through different ways, depending on its origin or nature. For example, the analyte can be separated from the interferent matrix before measurement of fluorescence. Time resolution may be useful when background fluorescence has a different decay time from that of the analyte. Measurement of analyte fluorescence must be done at wavelengths at which other sample components do not absorb or fluoresce.

Fluorescent molecules are subject to intensity variations as a function of temperature. In general, the frequency of collisional deactivation with solvent molecules increases as the temperature increases. These collisions bleed energy from the excited state and a fluorescence intensity decrease results. Temperature coefficients are typically 1–2% per °C. A thermostated sample cell is recommended to ensure temperature control both in samples and in standards.

Photodecomposition can be a serious problem in fluorescence during exposure to the exciting radiation. The degree of photodegradation is proportional to the exposure time and to the incident radiant power. Photodegradation can be minimized through the use of a longer-wavelength excitation band of the analyte, if one is available, or through the use of smaller excitation slit width in order to reduce the incident radiant power.

## Analytical Techniques

### Steady-State Fluorescence

The most widely used analytical approach in fluorescence is the use of steady-state fluorescence, where the intensity of the emitted light by the fluorochrome is measured. In general terms, the intensity of emitted light,  $I_f$ , that is measured by the instrument is

proportional to the fluorochrome concentration and can be described by the following relationship:

$$I_f = 2.303 \Phi_f I_0 \epsilon b c$$

where  $I_f$  is the observed fluorescence,  $\Phi_f$  is the quantum yield,  $I_0$  is the power of the incoming light,  $\epsilon$  is the molar extinction coefficient,  $c$  is the fluorophore concentration, and  $b$  is the optical pathlength. If  $\Phi_f$ ,  $I_0$ ,  $\epsilon$ , and  $b$  remain constant, the relationship between the fluorescence intensity and the fluorophore concentration is linear. This linearization is valid only for cases where  $\epsilon b c < 0.05$  (diluted solutions). Above this value, nonlinearity occurs. At higher concentrations significant absorption of the excitation beam radiation may take place (primary absorption), thus reducing the number of excited molecules across the light path. This effect causes negative deviation in a concentration–response plot. Also, if the excitation and emission spectra overlap, significant absorption of the emission beam takes place at high analyte concentrations, thus causing further nonlinearity (secondary absorption). The secondary absorption, when due to the analyte, is specifically denoted as self-absorption. Primary and secondary absorption together are called the inner filter effect.

### Fluorescence Quenching

The fluorescence signal generated by a molecule can be strongly altered by its environment. Apart from inner filter effects, the interaction of the fluorochrome with its surroundings is another way in which its fluorescence intensity can be decreased. This process is known as quenching. There are two kinds of quenching processes: (1) dynamic quenching and (2) static quenching. The efficiency of the two processes is dependent on the concentration of the quencher molecules.

Dynamic quenching or collisional quenching normally refers to nonradiative energy transfer from excited species to other molecules:

Here, the excited analyte molecule,  $F^*$ , transfers excitation energy to a quencher molecule,  $Q$ , causing deactivation of  $F$  and forms an excited quencher molecule,  $Q^*$ . For collisional quenching, the decrease in intensity often follows the well-known Stern–Volmer equation:

$$I_0/I = 1 + K[Q] = 1 + k_q \tau_0 [Q] \quad [1]$$

where  $I_0$  and  $I$  are the fluorescence intensities for the analyte in the absence of quencher and presence of quencher at concentration  $[Q]$ , respectively,  $K$  is the

Stern–Volmer quenching constant,  $k_q$  is the bimolecular quenching constant, and  $\tau_0$  is the unquenched lifetime. The Stern–Volmer quenching constant can be estimated from a plot of  $(I_0/I) - 1$  as a function of the quencher concentration. Equation [1] shows that the effect of a quencher decreases as the sample is diluted because the probability of collision between the analyte and the quencher is minimized. Also, the probability of collisions between the excited fluorophore and the quencher is higher as higher is the lifetime of the fluorophore. A wide variety of molecules can act as collisional quenchers, among which small molecules such as oxygen, halogens, amines, and electron-deficient molecules like acrylamide are good quenchers for some fluorophores, particularly if the fluorescence lifetime is greater than 10 ns.

In static quenching, the quencher and the fluorophore in the ground state form a stable complex. The process can be described by the following mechanism:

In this case, fluorescence is only observed from the unbound fluorophore. The decrease in fluorescence intensity is described by eqn [1] where  $K$  must be replaced by  $K_q$ , the constant of complex formation ( $K_q = [FQ]/[F] \times [Q]$ ). An example of this type of interaction is the quenching of ethidium bromide by caffeine.

In contrast to dynamic quenching, static quenching does not show an additional dependence on the lifetime of the excited state of the fluorophore. On the other hand, while formation of a complex just reduces the concentration of the free fluorophores without affecting the lifetime of the excited molecules, the lifetime of the complex is significantly longer than the lifetime of the excited fluorophore. So, measurement of the lifetime provides a means of distinguishing between dynamic and static quenching. Quenching studies provide direct information about diffusion of small molecules in solutions, in cellular tissues and in solid materials, and hence give insights into solvent or solid viscosities and/or accessibilities.

### Energy Transfer

In contrast to fluorescence static or dynamic quenching, for which a coupling between electronic orbitals

is necessary, energy transfer can also take place over large distances (up to 100 Å) without collisions. It occurs between two fluorescent molecules when one, the donor, absorbs a photon, elevating an electron to a higher energy state and, through resonance, the excitation of this electron is passed to another electron in the second, the acceptor. This energy is then re-emitted as a photon that is less energetic, and therefore of longer wavelength than the photon initially absorbed. The emitted radiation from the acceptor is termed sensitized fluorescence as it is observed without direct excitation of the acceptor. For energy transfer, some basic conditions must be satisfied:

1. the donor molecule must be a fluorophore with a sufficiently long fluorescence lifetime;
2. the emission spectrum of the donor and the excitation spectrum of the acceptor must overlap partially; and
3. the distance between donor and acceptor must be within a limiting range (usually 20–50 Å).

The rate of energy transfer ( $k_T$ ) to a specific acceptor is given by

$$k_T = \tau_D^{-1} (R_0/R)^6 \quad [5]$$

where  $\tau_D$  is the luminescence lifetime of the donor,  $R$  is the distance between the donor and the acceptor, and  $R_0$  is the critical distance (Föster distance) between the donor–acceptor pair for which the probability of energy transfer and the deactivation of the donor by radiative and nonradiative processes is the same. When the donor–acceptor distance is equal to the Föster distance, the transfer efficiency is 50%. Energy transfer is widely used in biochemistry to measure protein association, distances between two sites on a macromolecule, and the effects of conformational changes on these distances. It is a powerful method for obtaining both structural and dynamic information about macromolecules and macromolecular complexes.

### Synchronous Fluorescence

A synchronous spectrum, with a constant energy difference ( $\Delta\nu$ ), is performed by scanning the emission monochromator at a slightly faster rate than the excitation monochromator ( $\Delta\lambda = \lambda_{em} - \lambda_{ex}$ ). Synchronous spectra are strongly dependent on the wavelength offset. Ideally, only one peak is obtained when  $\Delta\nu$  is set to the Stokes shift of the fluorophore of interest. The main purpose of synchronous scanning is to generate spectra having decreased

bandwidths. Synchronous scanning may decrease the extent of overlapping in the spectra of mixtures of fluorescent compounds in multicomponent fluorescence applications.

### Time-Resolved Fluorescence

In contrast to steady-state fluorimetry, time-resolved fluorimetry is based on the measurement, at a fixed wavelength, of fluorescence signal as a function of time. For these measurements, the sample is exposed to a pulse of light (pulse fluorimetry), where the pulse width is short in comparison with the excited state lifetime of the fluorescent molecule. The decay of the fluorescence is then recorded with a high-speed detection system (nanosecond timescale). An alternative technique, phase-modulation fluorimetry (often called frequency-domain fluorimetry), uses a source that is amplitude-modulated at one or more frequencies. Measurement of the phase or demodulation of the fluorescence signal can be used to generate fluorescence decay times and time-resolved fluorescence spectra. Commercial instrumentation is available for these types of measurements. Time-resolved spectra or measurement of fluorescence decay times reveal much of the molecular information available from fluorescence. For example, it is possible to distinguish: (1) sample constituents whose fluorescence spectra overlap one another; (2) between static and dynamic quenching; and (3) the fluorescence of an analyte from background scattering.

### Fluorescence Anisotropy

Anisotropy measurements are based on the photoselective excitation of fluorophores by plane-polarized light. In an isotropic medium, the fluorophores are randomly oriented. Upon excitation with polarized light, those fluorophores whose absorption transition dipole is aligned parallel to the electric vector of the excitation, will be preferentially excited. If the molecule rotates and tumbles out of this plane during the excited state, light is emitted in a different plane from the excitation light. The intensity of the emitted light can be monitored in vertical and horizontal planes and thus, fluorescence anisotropy ( $r$ ) and polarization ( $P$ ) are defined by:

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \quad [6]$$

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \quad [7]$$

where  $I_{\parallel}$  and  $I_{\perp}$  are the fluorescence intensities of the vertically ( $\parallel$ ) and horizontally ( $\perp$ ) polarized

emission when the sample is excited with vertically polarized light. Anisotropy and polarization are both expressions for the same phenomenon. Fluorescence polarization measurements are widely used in molecular biophysics and biochemistry for studying rotational motions of electronically excited molecules, to detect the binding of relatively small molecules to macromolecules, to quantify protein denaturation, internal dynamics of proteins as well as in fluoroimmunoassay procedures.

### Fluorescence Performance Characteristics

The major advantage of fluorescence methods is sensitivity. One can see why fluorimetric methods are so sensitive if we compare them with absorption spectroscopy. In absorption methods, the absorbance of a compound in the range of  $1.0 \times 10^{-3}$  absorbance units can be measured using a good absorption spectrophotometer. Assuming a very efficient absorber with an extinction molar coefficient of  $\epsilon \cong 1 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$ , we can calculate a low detection limit  $C_{DL}$  of:

$$C_{DL} \cong 1.0 \times 10^{-3} / 1 \times 10^5 = 1 \times 10^{-8} \text{ mol l}^{-1}$$

using a 1 cm cell. On the other hand, for efficient luminescent molecules, with a good spectrofluorimeter in a low-background solution, detection limits in fluorescence spectroscopy easily approach concentrations in the range of 1–10 pM. Consequently, detection limits in fluorescence spectroscopy are generally more than three orders of magnitude better than those achieved for the same molecules in absorption spectroscopy. For example, the best experimental detection limit for efficient fluorescein, an efficient fluorophore, is  $\sim 0.1 \text{ pM}$ , using laser excitation and prepurified solvents. Using laser-induced fluorescence detection in capillary electrophoresis, detection limits of 0.1–100 amol (1 nl injection volume) have been reported for amino acids (precolum derivatization with dicarbocyanine fluorophore).

Precision, at concentrations well above the detection limit, is typically in the range 0.5–2% and it is limited by noise. In addition, sample treatment and calibration must be considered.

With external standardization, an equivalent analyte concentration in the standard and sample should yield the same analyte fluorescence signal. The accuracy of the determinations is dependent on interferences, chemical equilibrium involving the analyte, scattering, and quenching. Analyte interference due to absorption, scattering, or quenching may be

eliminated by dilution if the detection limit is low. Also, standard additions can be useful in these cases.

The linear range of molecular fluorescence can be four to six orders of magnitude for efficient fluorophores with low detection limits. As previously described, nonlinearity begins to occur at analyte concentrations where inner filter effects become significant.

## Applications

Fluorescence spectroscopy is one of the most widely used molecular spectroscopic techniques in the fields of molecular biology, biophysics, and biochemistry. Some important applications have already been outlined above, while describing the different fluorescent methods. Major classes of applications of fluorimetry include the following:

1. Determination of trace-level species, in clinical, biological and environmental samples, including inorganic species (metal ions, anions), organic, and biochemical compounds. Direct determination of inorganic species through the formation of fluorescent chelates may be very sensitive. This approach works well for diamagnetic metal ions as paramagnetic ones tend to quench fluorescence through intersystem crossing. Typical chelators include 8-hydroxy-quinoline and derivatives, morine and related flavonols, benzoine, etc. Indirect methods are based on measuring the quenching of fluorophores by inorganic species. This approach lacks sensitivity and selectivity. Among the organic species of environmental concern, polycyclic aromatic hydrocarbons are the most common analytes. Direct detection is possible for analytes of biomedical interest, such as FAD, NAD, porphyrins, and aromatic amino acids (endogenous fluorescence). For nonfluorescent compounds indirect detection is used by derivatization using selective fluorescent probes. Most proteins and peptides can be directly labeled with fluorophores via their available amine (lysine side chains) or thiol (cysteine side chains) groups. Isothiocyanates, such as fluorescein (FITC) and tetramethylrhodamine isothiocyanate (TRITC) are amine-reactive and are widely used for labeling. Succinimidyl esters react with thiol groups and sulfonyl chlorides (e.g., dansyl chloride) are reactive with amines and thiol groups. Fluorescent enzyme and immunoassays are widely used to determine a variety of analytes of biological and clinical interest.

2. Proteins, peptides, and nucleic acid labeling in molecular biology research. The fluorescence modification of nucleic acid molecules can be achieved in a number of ways. For example, fluorescent DNA

probes can be prepared chemically by preparing 5'-amino-end-labeled oligonucleotide probes on a DNA synthesizer. The use of fluorescent probes for *in situ* hybridization is sometimes referred to as FISH. Fluorescent DNA probe can also be prepared from template DNA by enzymatic methods (polymerases can incorporate dUTPs, dATPs, and dCTPs that have fluorescent dyes attached by linker arms to the nucleotide base). An exciting new development is the use of molecular genetic methods to fuse the gene for the green fluorescent protein (intrinsic fluorophore) to other target genes for subsequent expression in living cells.

3. Combination of fluorescence spectroscopy with flow and image cytometry is a powerful tool for diagnostic, prognostic and therapy control procedures in medicine as well as in the study of cellular aspects in immunology, cancer research, molecular biology, and biotechnology.

4. Multicomponent analysis using powerful fluorescence lifetime discrimination approaches.

5. As detection method in separation techniques, especially in thin-layer chromatography, high-performance liquid chromatography (HPLC) and electrophoresis. In HPLC applications for non-fluorescent compounds, either precolumn or postcolumn fluorescent derivatization is used. In capillary electrophoresis, the use of a laser to directly excite fluorescent compounds allows a extremely high sensitivity (femtomole to attomole levels of analytes can be detected in nanoliter volumes).

6. Automated batch and continuous flow analysis, widely used in clinical laboratories where high sample throughput is critical.

7. Studies of the microenvironment of fluorescent probe molecules. Many environmental factors modify the fluorescent properties of a molecule, e.g., solvent polarity, pH, proximity, and concentration of quenching species. The changes experienced by the fluorophore, sometimes subtle, can be used to obtain information about the specific region in which the fluorophore is localized.

8. Fluorescent sensors in solution (chemosensors) and fiberoptic sensors. Fluorescence is a particularly important technique in this field because of its high sensitivity of detection down to a single molecule, subnanometer spatial resolution with submicrometer visualization and submillisecond temporal resolution.

## Introduction

Fluorescence spectrometers capable of measuring excitation and emission spectra as well as fluorescence intensities have been commercially available for almost 50 years. While the functions and the overall layout of the main components have not changed very much over that period, the individual components have developed enormously in terms of sensitivity, stability, and longevity, with the result that modern instruments have capabilities far superior to those 50 years ago. Moreover, many accessories, which were either unobtainable or unusual in the 1950s are now routinely available, allowing the selectivity as well as the sensitivity of fluorescence methods to be more fully exploited. Another major change, characteristic of the last two decades, has been the universal use of personal computers to control the instruments as well as to record and manipulate the data. This rapid data processing capability has further enhanced the capabilities of fluorescence spectroscopy. This article summarizes the optical layout used in virtually all commercial instruments, and describes the main components used in modern spectrometers.

## Instrument Layout

The layout of the major fluorescence spectrometer components is shown in **Figure 1**. The characteristic feature of this arrangement is that any fluorescence emitted by the sample is detected at  $90^\circ$  to the incident light beam. This geometry, pioneered by Stokes in the 1850s, is still used in virtually all commercial and laboratory-built fluorescence instruments, inevitably with many additions, variations,

**Figure 1** Block diagram of the principal components of a fluorescence spectrometer.

and accessories for individual applications. Its crucial advantages are that photons transmitted by the sample (the majority of the incident photons when dilute solutions are studied) are not detected, and that Rayleigh scattered light has a minimum intensity in the  $90^\circ$  direction. The key optical elements of the layout are the light source, the excitation monochromator or filter (M1), the sample cell, the emission monochromator or filter (M2), and the detector. Separate power supplies are normally provided for the light source and the detector, and additional power may be needed for such items as a reference detector, sample stirrer, etc. This article deals only with steady-state fluorescence instruments: systems for studying lifetimes are summarized in a separate article.

## Introduction

Fluorescence spectrometers capable of measuring excitation and emission spectra as well as fluorescence intensities have been commercially available for almost 50 years. While the functions and the overall layout of the main components have not changed very much over that period, the individual components have developed enormously in terms of sensitivity, stability, and longevity, with the result that modern instruments have capabilities far superior to those 50 years ago. Moreover, many accessories, which were either unobtainable or unusual in the 1950s are now routinely available, allowing the selectivity as well as the sensitivity of fluorescence methods to be more fully exploited. Another major change, characteristic of the last two decades, has been the universal use of personal computers to control the instruments as well as to record and manipulate the data. This rapid data processing capability has further enhanced the capabilities of fluorescence spectroscopy. This article summarizes the optical layout used in virtually all commercial instruments, and describes the main components used in modern spectrometers.

## Instrument Layout

The layout of the major fluorescence spectrometer components is shown in **Figure 1**. The characteristic feature of this arrangement is that any fluorescence emitted by the sample is detected at  $90^\circ$  to the incident light beam. This geometry, pioneered by Stokes in the 1850s, is still used in virtually all commercial and laboratory-built fluorescence instruments, inevitably with many additions, variations,

**Figure 1** Block diagram of the principal components of a fluorescence spectrometer.

and accessories for individual applications. Its crucial advantages are that photons transmitted by the sample (the majority of the incident photons when dilute solutions are studied) are not detected, and that Rayleigh scattered light has a minimum intensity in the  $90^\circ$  direction. The key optical elements of the layout are the light source, the excitation monochromator or filter (M1), the sample cell, the emission monochromator or filter (M2), and the detector. Separate power supplies are normally provided for the light source and the detector, and additional power may be needed for such items as a reference detector, sample stirrer, etc. This article deals only with steady-state fluorescence instruments: systems for studying lifetimes are summarized in a separate article.

## Light Sources

The fluorescence signal from a sample in dilute solution is (if photodecomposition effects are ignored) proportional to the incident light intensity. Thus the light source for fluorescence spectroscopy should have an intense and stable output. Other desirables

include the availability of a wide range of excitation wavelengths, long life, low cost, and the absence of hazards. In practice no single light source has all these properties, and several types of source thus find widespread use.

In instruments designed for routine laboratory work, two types of xenon lamps now predominate. Continuous wave (CW) xenon lamps, usually with a power consumption of 150–450 W, provide intense sources covering wavelengths from  $\sim 230$  nm into the near-infrared (**Figure 2**). Such lamps have a thick quartz or silica envelope and are filled with xenon gas at a pressure (at room temperature) of several bars. A high voltage ( $\sim 30$  kV) is used to strike an arc between two metal electrodes a few millimeters apart. Once the arc is established, a stable emission is maintained by running the lamp in low voltage, high current conditions: a 150 W lamp might operate at  $\sim 7.5$  A, 20 V. Clearly such lamps need special power supplies. Their high intensity and wide wavelength range explains their great popularity over  $\sim 50$  years. However, they have several disadvantages, including a lifetime of only a few hundred hours before the arc becomes unstable and impossible to focus on the excitation monochromator. Moreover, the lamps are costly and generate toxic ozone gas (removed by thermal decomposition or an adequate exhaust system). Their operating pressures of 70–100 bar demand the provision of sturdy steel housings for safety reasons. Very occasionally such lamps fail catastrophically while in use: a loud explosion then fills the inside of the spectrometer with tiny fragments of shattered silica and metal, a major problem.

In the last 20 years xenon flash-tubes have become popular alternative light sources. These tubes have a

similar spectral profile to their more formidable cousins (**Figure 2**) but are operated in a pulsed mode. The average power supplied is only a few watts but pulses of up to 10 kW are applied to the lamp at the line frequency (e.g., 50 or 60 Hz, according to the country of use). This causes very bright and short-lived ( $10\text{--}20\ \mu\text{s}$ ) flashes of light to be generated, the resulting pulses of fluorescence being collected, accumulated, and determined by a time-gated detector system (see below). These flash-tubes may have a rather longer life than the high power xenon lamps (though they are still costly,  $\sim$ US\$500), are safer, and generate very little ozone. Their main advantage is that the pulsed source, time-gated system can be used to distinguish short-lived light signals (fluorescence, scattered light) from long-lived ones (phosphorescence and other delayed emissions). In routine analyses, instruments using such sources have sensitivities similar to, or perhaps slightly poorer than, those using CW xenon lamps.

Conventional light sources sometimes used in simpler and older instruments include tungsten and other incandescent lamps, which are only applicable at excitation wavelengths longer than  $\sim 350$  nm, and mercury vapor lamps, which emit light almost solely at characteristic atomic wavelengths. The principal mercury lines are at 254, 313, 365, 405, 436, and 546 nm, depending upon the pressure in the lamp (higher pressure lamps give the longer wavelength lines). These sources are very stable and long-lasting and can be very intense, but they restrict the choice of excitation wavelengths and prohibit the collection of excitation spectra (see below). Some mercury lines are especially useful: many visible region fluorophores can be excited at 365 nm, and the 546 nm line is well matched to rhodamine fluorophores. Moreover, the lines can be used to calibrate monochromator accuracy.

The extremely bright light output of lasers seems to make them ideal sources for fluorescence, but their use has become commonplace only in recent years. This is partly due to concerns over cost and reliability, but other photophysical factors are also important. A single-wavelength laser is only useful if its emission is well matched to the fluorophore(s) under study; and a very intense light source may cause photodecomposition of the sample. The availability of very cheap, reliable, and stable diode lasers has made a big difference. Earlier sources of this type had emission lines in the red and near infrared regions ( $\geq 630$  nm) and their availability coincided with the growth of interest in long wavelength fluorescence, with its advantages of reduced scattered light interference, less background fluorescence from biological samples, and reduced photodecomposition. Diode

**Figure 2** Spectral output of a typical xenon arc lamp.

lasers with wavelengths in the blue and violet regions are now available, and their increased use is inevitable. Also valuable are the latest light-emitting diodes (LEDs), the so-called 'super(ultra)bright' LEDs. Many wavelengths are available, e.g., 375, 400, 420, 430, 450, 470, 505, 525, 570, 610, 630, and 660 nm, with bandwidths of 10–70 nm. A 375-nm LED with an emission bandwidth of only  $\sim 12$  nm is now available, and is marketed with fluorescence excitation specifically intended. Super-bright white LEDs covering a wide range of visible wavelengths (corresponding to a color temperature of  $\sim 5500$  K) are now also available. Most LEDs typically cost only a few dollars each, have lifetimes of many thousands of hours, and can be pulsed for time-gated applications. Such cheap, stable, and simple sources will certainly become more common, especially in compact and robust instruments for use in the field, in doctors' offices, etc.

### Excitation Monochromator or Filter (M1)

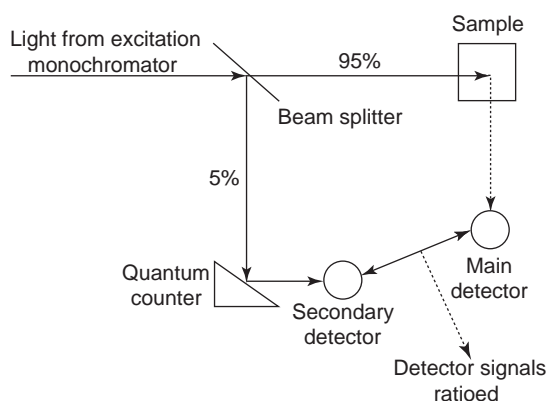

When a broadband light source (xenon lamp, incandescent lamp, pumped dye laser, or LED) is used in fluorescence measurements, it is necessary to restrict the bandwidth of excitation of the sample. This selection is an intrinsic part of the selectivity of the technique. Interference filters can be used to select suitable excitation wavelengths. They have bandwidths (measured between wavelengths at which their transmission efficiency is 50% of the maximum) of 10–20 nm. Mounted in holders or filter wheels, they allow the excitation wavelength to be changed easily according to the fluorophore studied. The maximum transmission of such filters in the visible region is as high as 80% (lower in the ultraviolet region), so they do not seriously compromise sensitivity. Equally they do not permit the study of excitation spectra, or of the best compromise between selectivity and sensitivity for a given fluorophore (see below). In modern instruments a grating monochromator (M1) is thus usually provided, consisting typically of an entrance slit on to which the light source is focused, a holographic reflection grating, and an exit slit. Several different monochromator designs are available, and are described in standard texts on optics and spectroscopy. In some cases a double monochromator is provided, with two gratings, etc., but the resultant reduction in stray light is offset by a loss of light throughput and of measurement sensitivity. A small motor allows M1 to be scanned at a variety of speeds: modern instruments provide speeds up to  $500 \text{ nm s}^{-1}$  to facilitate

'prescan' operations (see below) and allow rapid scans of samples in flow cells. Slit-widths are adjustable, in steps or continuously, to give control of the spectral pass-band of the monochromator. As the latter is decreased, selectivity of excitation of one fluorophore over another may improve, but the light throughput is lowered, so analytical sensitivity is lost. Conversely large slit-widths provide higher sensitivity at the cost of poorer selectivity and poorer rejection of scattered light.

When narrow line light sources are used, a scanning monochromator is largely redundant, so an interference filter will be sufficient, e.g., to isolate one mercury lamp emission line or one line from multi-line laser such as an argon-ion laser. Single-line lasers such as simple diode lasers need no filter or monochromator at all in the excitation beam.

### Reference Beam Systems

A striking feature of the optical layout in **Figure 1** is that a fluorescence spectrometer is essentially a single-beam instrument. Thus fluctuations in light source intensity cause corresponding changes in fluorescence signals. Moreover, the efficiency of the grating in the monochromator M1 will be wavelength dependent (optimum M1 efficiencies at  $\sim 300$  nm are common). So when the excitation spectrum of a sample is measured, by scanning M1 at a fixed emission wavelength, the spectrum obtained will reflect the source and grating properties as well as those of the sample. Such spectra are said to be 'uncorrected', and if routinely used they would complicate comparisons between the results obtained on different instruments. As a result, almost all spectrometers with an excitation monochromator now also include a reference beam system (**Figure 3**). The first essential component of such a unit is a beam-splitter placed between the exit slit of M1 and the sample, which in a wavelength independent manner diverts a small fraction ( $\sim 5\%$ ) of the excitation beam to a quantum counter. The latter contains a concentrated solution of a carefully selected long-wavelength dye, and emits a fluorescence signal that is proportional to the intensity of light falling on it, 'irrespective of the wavelength of the latter'. This emission from the quantum counter falls on to a secondary photodetector. The output of the latter is compared with that of the spectrometer's main detector (see below), thus allowing light source fluctuations to be cancelled out and excitation spectra to be 'corrected' so that results from different instruments should be comparable. (Accuracy and repeatability in a given monochromator should be  $\sim \pm 1$  nm.) These techniques are

**Figure 3** Components of the reference beam system in a spectrometer providing corrected excitation spectra.

described in more detail in texts on fluorescence standards (see Further Reading section).

## Sample Compartment

Light exiting the monochromator M1 is directed by the exit slit and/or a lens on to the sample in a suitable cell. In most cases a vertical slit image is focused on to the cell, but some instruments use a horizontal slit and claim improved sensitivity. Many instruments provide a shutter between M1 and the sample to protect the latter from heating and photodecomposition effects until the moment when measurements begin. In conventional solution measurements, samples are held in silica, glass, or disposable plastic cuvettes with four polished faces and pathlengths of 10 mm or less. Only two adjacent faces of a cuvette are used, but experiments have shown that giving the two remaining surfaces reflective coatings to increase the fluorescence signal is counterproductive, as the scattered light is also increased very greatly. Since fluorescence is emitted in all directions by the sample, only 5–10% of the emitted photons are in practice detected in a conventional instrument.

It is useful for the cell holder position to be adjustable so that the crucial portion of the sample that is illuminated by the light source and observed by the detector is offset from the center of the cuvette: this helps to minimize inner filter effects. Some commercial instruments provide this facility. A great range of flow cells for use in flow analysis and high-performance liquid chromatography detection is available: these generally have very short optical pathlengths, so inner filter effects are much less likely.

Since fluorescence intensities are temperature dependent by up to  $-3\%$  per degree Celsius, the provision of a thermostat system to provide control to within  $\pm 0.1^\circ\text{C}$  is desirable, and both electrical and water circulation systems are in use. Among the

range of other sampling and measurement accessories available, the most important are:

1. Polarization facilities. Fluorescence polarization measurements are now very common. Dedicated instruments may provide a fixed excitation polarizer with a vertical orientation, and an electrooptic emission polarizer with either vertical (i.e., parallel) or horizontal (crossed) orientations. Routine instruments provide polarizing filters allowing a greater range of orientation combinations. The light transmission properties of these filters are wavelength dependent, and this restricts the ranges over which they can be used.
2. Fiber-optic links to provide microtiter plate reading facilities. The plate-reader may fit into the sample compartment itself, or be a separate external unit with fiber-optic connections. The sensitivity of such devices is generally thought to be less good than that of dedicated plate-readers. It is worth adding that fiber-optic based fluorescence instruments using only simple excitation and emission filters have often been used for remote sensing, field-work, etc. Fibers may be made of silica, glass, or plastics, according to the wavelength range under study, and many different optical layouts have been described.
3. A magnetic stirrer motor mounted under the cuvette holder. Stirring may facilitate rapid mixing, e.g., in kinetic studies, but if the stirring is too vigorous, the resulting turbulence in the sample will increase scattered light interference. Also useful is a sample compartment door with an injection port for adding reagents to a cuvette.
4. Systems to allow low temperature fluorescence (or phosphorescence) studies, with liquid nitrogen or other coolants. In some cases a Dewar flask with transparent walls is provided, so that the coolant lies in the light beam and surrounds the sample contained in a narrow silica capillary. Alternatively the sample capillary is cooled by conduction, being mounted against a copper rod whose upper end is immersed in the coolant.
5. Sample holders for thin solid samples such as pieces of paper, thin layer chromatography (TLC) plates, etc. The ability to study such materials is a major advantage of fluorescence spectroscopy, but the optical arrangement used requires careful design. If a solid surface is placed in the sample compartment at a  $45^\circ$  angle to both excitation and emission beams, a great deal of incident light is liable to be reflected directly into the emission beam, giving a very large background signal. This can be avoided by off-setting the angle at which the surface is observed, a range of devices with adjustable optics and orientations being available.

6. Stopped flow accessories, allowing kinetic measurements in the millisecond time domain. These quite complex accessories provide the necessary injection syringes, a mixer, usually in a T-configuration and with a short dead-time, low volume flow cells, etc.

## Emission Monochromator or Filter (M2)

After leaving the sample compartment, fluorescence and unwanted scattered light signals enter the emission monochromator or filter (M2) before passing to the detector. The function of M2 is to isolate the signal from the desired fluorophore and minimize signals from Rayleigh and Raman scattering and background fluorescence. As in the case of M1, this is possible using either a grating monochromator or one or more filters. In commercial instruments a reflection grating monochromator is usual, with its optimum efficiency at 400–500 nm, and again it will have adjustable slits to control its pass-band and be motor-driven at a variety of speeds. Such instruments often also include a selection of cutoff filters in the emission beam to eliminate ‘second-order scattered light’ effects. If the excitation wavelength is 300 nm, light at that wavelength will be scattered by the sample and will pass through M2 when the latter is set to 600 nm, using the second-order properties of the M2 grating. This artifact is easily removed by inserting a filter into the emission beam that will absorb the 300 nm light, but pass light of higher wavelengths. In practice a series of filters is offered, according to the excitation wavelength used.

The fluorescence spectrum (emission spectrum) of a sample is obtained by scanning M2 while keeping the excitation wavelength constant. Since the efficiency of M2 is wavelength dependent, and the detector (see below) also has a sensitivity that varies with wavelength, such a fluorescence spectrum is normally ‘uncorrected’, i.e., it will depend upon the instrument as well as the sample. The correction of emission spectra is less easy to achieve than for excitation spectra, and is less often performed, so published emission spectra often vary from instrument to instrument. At least three methods are available for emission correction. A sound but tedious method is to calibrate the emission system (i.e., M2 plus the detector) with a standard light source of known emission profile. Such devices are available from NIST and other standards bodies. Comparison of the output of the fluorescence spectrometer with the certified output of the lamp then provides a correction factor at each wavelength, which can be applied to subsequent sample spectra. A related technique is to

use the output of the instrument’s own (CW) light source, as measured by the quantum counter (see above) as the standard source, reflecting it into the emission beam using a special sample compartment accessory. This method suffers from the disadvantages that it is difficult to achieve wavelength-independent reflection, and that any errors made in calibrating the excitation system are naturally carried into the emission correction process. Lastly it is possible to measure the fluorescence spectrum of a standard solute (e.g., quinine in perchloric acid) and compare the result with the published spectrum of the standard to give the correction factor at each wavelength. This method is only strictly valid if subsequent sample spectra are measured in the same optical conditions as the standard. Moreover, no single standard material can cover the wavelength range used in modern fluorescence applications. Spectral correction is covered in more detail in books given in the Further Reading section.

A fluorescence spectrometer with two monochromators with separate motor drives allows the measurement of several spectra in addition to the conventional excitation and fluorescence spectra previously described. The most important of these variants are synchronous spectra, obtained by scanning M1 and M2 simultaneously at the same scan rate and with a fixed wavelength interval,  $\Delta\lambda$ , between them (with M2 naturally at the higher wavelength). Compared with conventional spectra synchronous scans, with a judicious choice of  $\Delta\lambda$ , can be greatly narrowed and simplified, with a corresponding gain in selectivity. In principle a fluorophore mixture might be resolved using a single  $\Delta\lambda$  value, the synchronous spectral maxima for each component occurring at different wavelengths, or by using different values of  $\Delta\lambda$  for each component. Another method involves scanning the two monochromators at different rates, chosen so that the ‘frequency’ difference between them is constant. All these spectra, including conventional excitation and emission scans, can be regarded as sections through the excitation–emission matrix (EEM), also known as the total luminescence spectrum (TLS). This is a three-dimensional (3D) representation of the properties of a fluorescent sample, the  $x$ -,  $y$ -, and  $z$ -axes corresponding to excitation wavelength, emission wavelength, and intensity, respectively. In practice an EEM can be presented as a 3D picture, viewed from any angle, or by a mathematically equivalent contour plot. Both these facilities are commonly available on modern, PC-interfaced spectrometers.

In simple detectors, filters may replace the emission monochromator. Interference filters, with or without cutoff filters, are often satisfactory in

instruments dedicated to the measurement of a single fluorophore or a few known fluorophores. With laser light sources, holographic notch filters are very valuable, their sharp cutoff characteristics allowing measurements of fluorescence at wavelengths only a few nanometers above that of the laser. Another device sometimes used is a linear variable interference filter. In this device the spacing between its optical elements changes along its length. As it moves through the emission beam the wavelengths it transmits are continually changing, so it acts as a simple monochromator. Such devices can be used in the range 400–700 nm, their maximum transmission being typically ~40%.

## Detectors

Since only a small fraction of the fluorescence emitted by a sample is normally collected by the emission optics in a spectrometer, it is clearly essential for the instrument to have a sensitive and stable detector with a good response over the whole wavelength range provided by the monochromators. In conventional instruments, the detector is almost always a photomultiplier tube (PMT). These devices are ubiquitous in many areas of spectrometry and so will only be described briefly. They consist of an evacuated quartz or glass envelope containing a photocathode. When a photon falls on this cathode it emits an electron. This electron is focused on to a series of electron multipliers (dynodes) held at increasing potential differences, causing an amplifying shower of electrons, which eventually arrive at the anode and yield a measurable current. Such a detector requires its own power supply to provide the high potentials (several hundred volts) applied. A conventional PMT has its maximum response at ~450 nm, with a quantum efficiency of ~25%; the sensitivity usually falls off sharply above ~550 nm. 'Red-sensitive' PMTs giving good responses of 850–900 nm are now often used: they may have reduced sensitivities in the visible spectrum.

As noted above, instruments using pulsed light sources use a gated detector system to distinguish rapid from delayed light signals. The detector is synchronized to the source pulses and the user can control the delay time,  $t_d$ , between the start of the pulse and the opening of the detector gate, and the gate time,  $t_g$ , for which the detector is on in the period before the next pulse. Manipulation of these times allows the lifetimes of delayed fluorescence and phosphorescence to be estimated.

Miniature PMTs have recently become popular for use in compact or portable instruments. They can be

driven from relatively low voltage supplies. In routine work PMTs are normally used in DC mode, the total anode current they produce being amplified and recorded. But low light levels can be recorded using photon-counting PMT systems, in which each secondary electron pulse arriving at the anode in response to a single incoming photon is recorded on a high-speed counter. Such systems inevitably fail when the photon flux generates cathode electron pulses more quickly than the counter can operate.

Two types of solid-state detector have found many applications in fluorescence detection. Charge coupled device (CCD) arrays are well established in other areas of spectrometry, and will not be described in detail here. They allow the detection of a complete emission spectrum in a few milliseconds, the fluorescence monochromator output being dispersed across the array elements simultaneously. Arrays that plug directly into PC-interface cards are now available. A major advantage of these detectors is that their optimum sensitivity is at longer wavelengths (700–800 nm) than that of most PMTs, so they are well suited to near infrared fluorescence detection. Avalanche photodiodes (APDs) also have good long wavelength sensitivity and have been used successfully, especially in compact or portable detectors. They can be regarded as developments of simple silicon photodiodes, with semiconductor layers and their applied potentials arranged to produce many electrons and holes from each incident photon. Gains of several hundred are feasible with silicon APDs operating between 400 and 1100 nm, and are compact detectors, hard to overload.

## Instrument Control and Data Handling

Most modern fluorescence spectrometers are entirely PC-controlled, the case holding the optical components having only an on-off switch. The interfaced PC, equipped with suitable software, directs all routine operations of the spectrometer, including the type of spectrum to be scanned, scan rate, slit-widths, the delay, and gate times used with pulsed sources, the insertion of polarizing or other filters into the light beams, etc. Signals from the instrument are received and stored by the computer and can be further processed using smoothing or averaging methods, the calculation of derivative spectra, the presentation of EEM spectra, the analysis of mixtures by chemometric resolution of their overlapping spectra, and so on. Other facilities include the presentation of polarization spectra (the variation of fluorescence polarization with wavelength); recording fluorescence as a function of time, for example in kinetic assays; the

determination of the correction factors needed for corrected spectra; and the useful 'prescan' function, which provides rapid scans of both monochromators to suggest excitation and emission wavelengths for brand new samples. As in most areas of spectroscopy, the use of a PC-controlled instrument is now obligatory for all but the most routine analyses, and as PCs grow in speed and power, their value increases correspondingly.

## Introduction

Fluorescence spectroscopy has been established as an analytical technique for both qualitative and quantitative analysis because of its inherent sensitivity, selectivity, and versatility. The selectivity of fluorescence measurements can be attributed to the multiparametric properties of the measurements. This is because even the simplest of luminescence measurements will involve the use of two parameters: an excitation wavelength and an emission wavelength. In a conventional fluorescence measurement, the excitation wavelength is set at a particular value and the emission wavelengths are scanned. Various analytical methods that employ conventional fluorescence measurements exist for the detection and quantification of single-component analytes. These analytes can range from environmental pollutants to pharmaceutical compounds, from marine algae to biological fluids. The fluorescence-based methods usually have impressive limits of quantification. However, these measurements tend not to be highly selective for multicomponent samples (two or more components) since conventional fluorescence measurement usually involves the use of a single excitation and emission wavelength setting in order to achieve the best signal response.

In the case of a multicomponent sample (real-world samples), the resultant fluorescence emission spectrum is often a combination of those of the components in the mixture that are excitable at the chosen excitation wavelength. This can result in broad and severely overlapping emission spectra. Qualitative and quantitative information is all but lost from such spectra. Furthermore, a single-wavelength scan does not offer the possibility of suppressing the fluorescence contributions of some compounds while analyzing only selected components in the mixture.

It is apparent from the scenario described above that conventional fluorescence methods are of limited applicability for the analysis of multicomponent mixtures. Therefore, for routine laboratory analysis of a multicomponent mixture, the most important prerequisite is to develop a simple and easy-to-use qualitative and quantitative fluorescence-based method that is not limited to single-component samples. Additionally, the fluorescence technique adopted should not sacrifice the sensitivity and selectivity of conventional fluorescence measurements and should minimize the problem of overlap in emission spectra of complex multicomponent samples.

To overcome the limitations of single-wavelength measurements in evaluating multicomponent samples, multidimensional luminescence measurements can be used. The multidimensional approach allows for a better estimation of minor differences between the individual components of the mixture and can ultimately lead to well-resolved spectra of multicomponent mixtures. Of significant importance is the fact that multidimensional luminescence measurement can be a viable technique for detecting minute and distinct spectral perturbations from small analytical samples.

As far as the potential application of multidimensional fluorescence measurements is concerned, the

determination of the correction factors needed for corrected spectra; and the useful 'prescan' function, which provides rapid scans of both monochromators to suggest excitation and emission wavelengths for brand new samples. As in most areas of spectroscopy, the use of a PC-controlled instrument is now obligatory for all but the most routine analyses, and as PCs grow in speed and power, their value increases correspondingly.

## Introduction

Fluorescence spectroscopy has been established as an analytical technique for both qualitative and quantitative analysis because of its inherent sensitivity, selectivity, and versatility. The selectivity of fluorescence measurements can be attributed to the multiparametric properties of the measurements. This is because even the simplest of luminescence measurements will involve the use of two parameters: an excitation wavelength and an emission wavelength. In a conventional fluorescence measurement, the excitation wavelength is set at a particular value and the emission wavelengths are scanned. Various analytical methods that employ conventional fluorescence measurements exist for the detection and quantification of single-component analytes. These analytes can range from environmental pollutants to pharmaceutical compounds, from marine algae to biological fluids. The fluorescence-based methods usually have impressive limits of quantification. However, these measurements tend not to be highly selective for multicomponent samples (two or more components) since conventional fluorescence measurement usually involves the use of a single excitation and emission wavelength setting in order to achieve the best signal response.

In the case of a multicomponent sample (real-world samples), the resultant fluorescence emission spectrum is often a combination of those of the components in the mixture that are excitable at the chosen excitation wavelength. This can result in broad and severely overlapping emission spectra. Qualitative and quantitative information is all but lost from such spectra. Furthermore, a single-wavelength scan does not offer the possibility of suppressing the fluorescence contributions of some compounds while analyzing only selected components in the mixture.

It is apparent from the scenario described above that conventional fluorescence methods are of limited applicability for the analysis of multicomponent mixtures. Therefore, for routine laboratory analysis of a multicomponent mixture, the most important prerequisite is to develop a simple and easy-to-use qualitative and quantitative fluorescence-based method that is not limited to single-component samples. Additionally, the fluorescence technique adopted should not sacrifice the sensitivity and selectivity of conventional fluorescence measurements and should minimize the problem of overlap in emission spectra of complex multicomponent samples.

To overcome the limitations of single-wavelength measurements in evaluating multicomponent samples, multidimensional luminescence measurements can be used. The multidimensional approach allows for a better estimation of minor differences between the individual components of the mixture and can ultimately lead to well-resolved spectra of multicomponent mixtures. Of significant importance is the fact that multidimensional luminescence measurement can be a viable technique for detecting minute and distinct spectral perturbations from small analytical samples.

As far as the potential application of multidimensional fluorescence measurements is concerned, the

method is highly selective and gives enhanced information about the components of a complex sample. Multidimensional fluorescence measurements have found wide application for the identification and quantification of polycyclic aromatic hydrocarbons (PAHs) in environmental samples, the fingerprinting and qualitative identification of fluorescent PAHs contained in oil-spill samples, the characterization and mapping of motor oil and gasoline samples in forensic studies, the characterization and analysis of pharmaceutical compounds, the resolution of complex clinical samples, bacterial fingerprinting and classification, and for the spectral fingerprinting of marine phytoplankton samples.

This technique also allows for the resolution of spectrally similar components and severely overlapping components in a multicomponent mixture. In addition, multidimensional fluorescence measurements provide significant spectral information for distinguishing between closely related samples. The variations in the excitation and emission profiles add to a full understanding of the minimum number of fluorescing components in the sample matrix.

A detailed account of progress in the applications of multidimensional fluorescence analysis in analytical chemistry can be found elsewhere. The purpose of this article is to outline the scope and potential practical applications of multidimensional fluorescence in analytical chemistry and other related research areas.

## Instrumentation

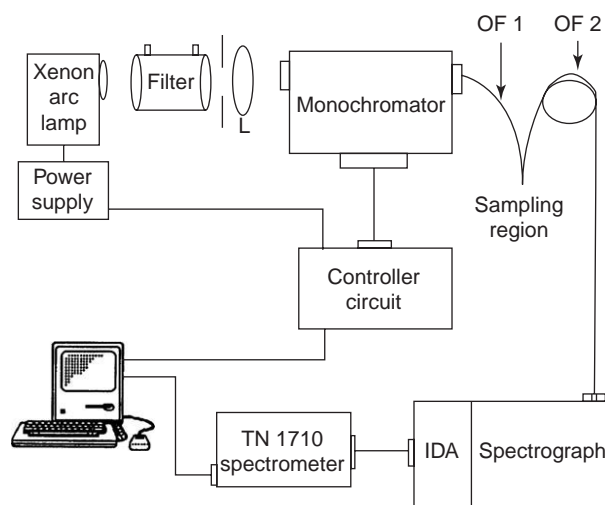

Instrumentation capable of acquiring conventional emission spectra can also be used to acquire data in a multidimensional format. However, the use of conventional fluorescence spectrophotometers can be very time consuming owing to the type of detector (photomultiplier) and wavelength selector (monochromator) that are often used. To reduce the time necessary to acquire the spectra and increase the efficiency of data collection, parallel detectors may be used. Parallel detection allows for the simultaneous acquisition of spectral data over a range of wavelengths (e.g., 200–700 nm). Parallel detection can significantly reduce data acquisition time and can result in an increase in the signal-to-noise ratio owing to the advantage of multichannel operation.

Instrumentation capable of acquiring data in a multidimensional format using parallel detectors is similar to that of conventional spectrofluorimeters. The major differences are the type of detector, light source, and wavelength selectors used. In a conventional fluorimeter, a photomultiplier tube is used as

the photon detector. Although the photomultiplier tube is a very sensitive detector, it is a single-channel detector and lacks the ability to monitor multiple wavelengths simultaneously. Thus, this type of detector is not suited for rapid acquisition of data over a range of wavelengths. Instead of using a photomultiplier tube as the photon detector, multichannel detectors that are capable of acquiring a range of wavelengths in a snapshot are used in multidimensional instrumentation. Multichannel detectors that have been used successfully for the collection of fluorescence spectra include the vidicon, linear photodiode array (PDA), silicon intensified target vidicon, and charge-coupled device (CCD).

Each of these detectors has its own unique advantages and disadvantages. The first generation of multidimensional fluorescence instruments ('videofluorimeters') used the vidicon for collecting the total luminescence spectrum. The vidicon, however, suffers from poor sensitivity and detector lag and blooming. To overcome this, the second generation of multidimensional instruments used linear PDAs. A schematic of a multidimensional fiber-optic instrument that incorporates a PDA for detection is shown in Figure 1. Commercial instruments now offer CCDs as detectors.

It is also important that the light source in a multidimensional instrument be able to provide relatively continuous output over a range of wavelengths, since multiple excitation wavelengths are needed in the multidimensional measurement. In order to use multiple excitation wavelengths, a white light source, such as a high-pressure xenon arc lamp,

**Figure 1** Schematic of a fiber-optic-based multichannel fluorometer: IDA = 512-element intensified linear photodiode array detector; L is the lens; and OF 1 and OF 2 are the excitation and emission fibers, respectively.

is used. The xenon arc provides intense and relatively continuous output throughout the ultraviolet and visible regions (200–1000 nm).

The new computerized spectrofluorimeters in combination with the availability of selective multi-channel detectors allow for a reliable and quick collection and analysis of spectral information that was difficult to accomplish using a single-wavelength scan. The new multichannel detectors used for making multiwavelength measurements also allow the ability to study a wide variety of multicomponent samples.

## Spectral Presentation

In multidimensional fluorescence measurement, the measured luminescence,  $I_L$ , is a function of the excitation ( $\lambda_{ex}$ ) and emission wavelengths ( $\lambda_{em}$ ), i.e.,

$$I_L = f(\lambda_{ex}, \lambda_{em}) \quad [1]$$

By varying either or both of the two wavelengths, the measurement of an individual fluorophore or complex mixture can be achieved.

It is often convenient to format multidimensional fluorescence data in the form of a matrix of intensities called the excitation–emission matrix (EEM). The EEM can be represented as the vector product of the excitation and emission spectra. Each EEM has the following characteristics:

1. Every row represents an emission spectrum excited at a specific excitation wavelength.
2. Each column represents the excitation spectrum at a specific emission wavelength.
3. Scattered light appears as a diagonal line across each EEM.

Data acquired in the form of an EEM or total luminescence spectrum can be conveniently presented either as an isometric projection or in the form of a contour map. When displayed as isometric projections, the EEM provides a three-dimensional intensity profile of the sample over the range of excitation and emission wavelengths scanned. One axis represents the emission wavelengths, while the second axis represents the excitation wavelengths. The third axis is the intensity. The diagonal ridge displayed across the EEM spectrum is due to first-order light scattering. A drawback of displaying the data in the form of isometric projections is that small peaks adjacent to more intense peaks tend to be partially or completely obscured. This prevents accurate viewing of the EEM.

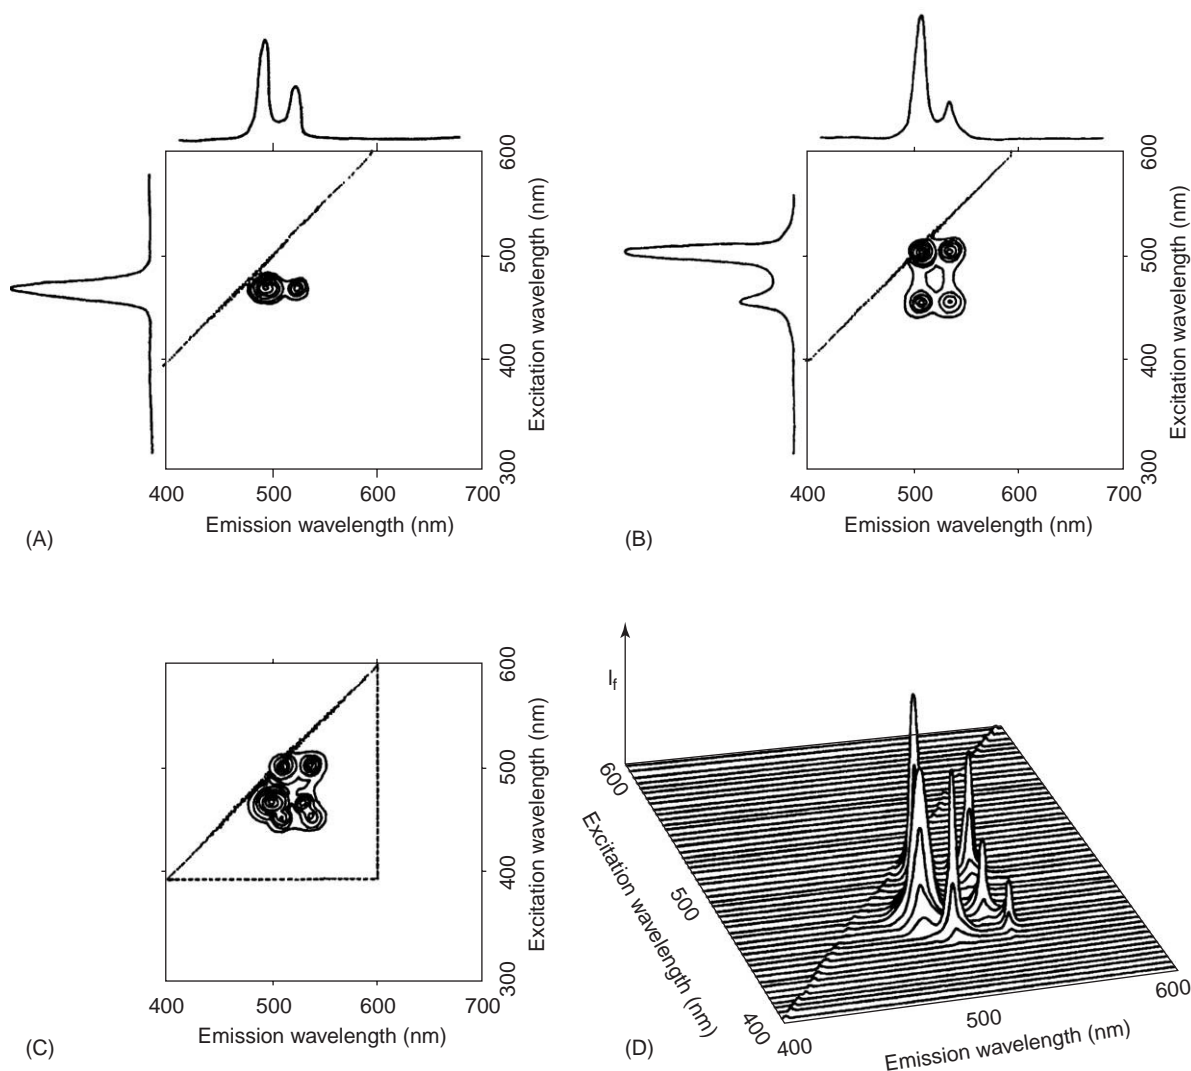

To overcome display problems, the data matrix can be represented in a more informative way, such as a contour map. In the contour plot presentation, the spectral information is plotted as a series of iso-emissive concentric lines in the excitation and emission wavelength plane. Often this technique permits the detection of possible peak overlap and allows for a better view of the spectral information. The primary advantage of the two-dimensional contour plot is that it successfully eliminates the problem of obscured peaks and thereby increases the possibility of identifying individual components in the mixture. Figure 2 shows hypothetical EEMs illustrating both the isometric projection and contour plots. The advantage of viewing the data matrix in a contour plot is illustrated.

## Spectral Data Processing

This section provides a brief overview of methods available for the processing of multidimensional data. Further evidence relating to multidimensional applications is in the use of rapid scanning modern instrumentation for monitoring time-dependent phenomena such as chemical equilibria, reaction kinetics, flow injection analysis, and enzymatic processes. These techniques allow the use of different experimental strategies to capture and store spectral data, thereby facilitating numerous possibilities for data processing and graphical representation. This in turn permits the use of various techniques to deconvolute overlapping spectra.

The acquisition of a single-wavelength fluorescence spectrum of a complex multicomponent mixture is more tedious for many analytical applications that involve the measurement of some essential intermediate components or transient species. The determinations of such systems become more critical if the spectral information for those species is important to the understanding and elucidation of the properties of the final product. Similarly, this is true for chemical measurements of components whose fluorescence intensity decreases continuously with time. A rapid multidimensional data-processing technique becomes exceedingly important in the analysis of these species in a chemical reaction.

The wavelength and time resolution of the EEMs of a multicomponent mixture are particularly important for the deconvolution of the mixture into individual constituents. A simple approach involves application of a ratio deconvolution method after obtaining a series of EEMs for the mixture of components by altering the relative intensities of components in each EEM. The EEM containing a mixture

**Figure 2** Generation of fingerprint excitation–emission matrix: (A) EEM of pure component, compound A; (B) EEM of pure component, compound B; (C) fingerprint EEM of a mixture of compounds A and B; (D) isometric projection of fingerprint in (C). (Reprinted with permission from Shelly DC, Quarles JM, and Warner IM (1980) Identification of fluorescent *Pseudomonas* species. *Clinical Chemistry* 26(8): 1127–1132.)

of components of different lifetimes will provide the characteristics necessary for ratio deconvolution. This will in turn allow for the necessary criterion to isolate individual components whose original spectra contained severely overlapping emission bands. The combination of multidimensional fluorescence measurements and ratio deconvolution is used in an attempt to accomplish satisfactory qualitative separation of mixtures containing components that have strong spectral overlap.

The emergence of new rapid scanning analytical instruments requires the processing of data with high dimensionality. This requires the development of multidimensional data filtering techniques and other modern processing methods. In many cases, the

interpretation of multicomponent chemical data is based on spectral matching and fingerprinting. The fingerprinting technique is employed for rapid qualitative characterization and identification of the properties and origin of the samples.

An added feature of total fluorescence techniques is found in systems whose emission and/or excitation wavelength maxima change with the formation of a complex. Multidimensional fluorescence analysis allows the analyst to detect the differences in sensitivity arising from changes in excitation and emission maxima of the analyte. In addition, the technique finds wide application in examining the corrected fluorescence spectra of clinical compounds and their derivatives. In studies involving biological

fluids, the sensitivity of the method is strongly influenced by changes in the excitation or emission peaks of the drugs when bound to target cells.

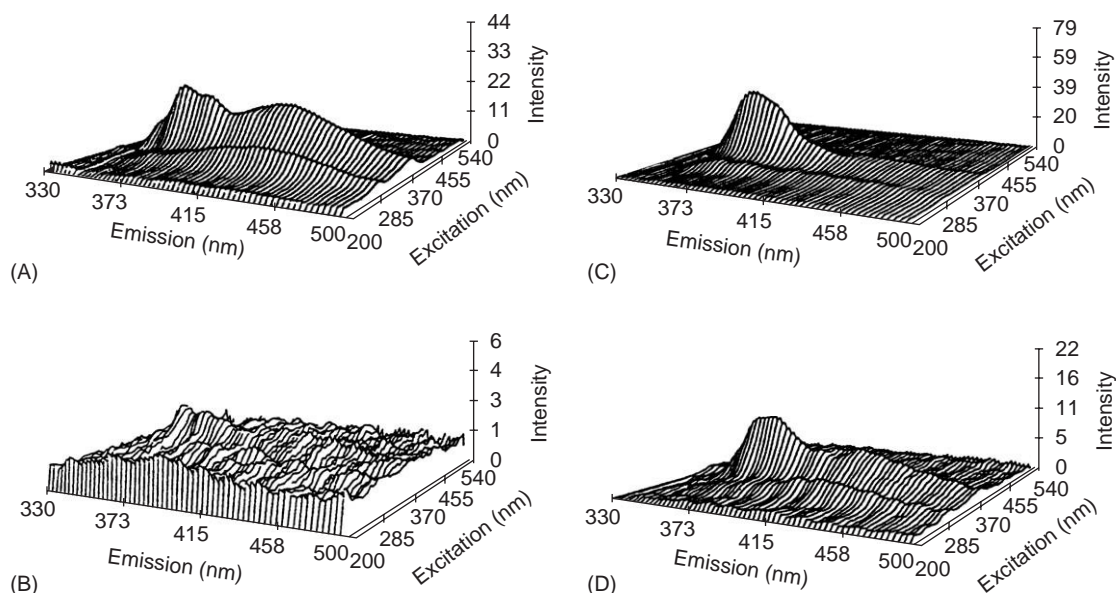

## Applications in Environmental Analysis

Multidimensional fluorescence analysis is well suited for routine qualitative separation and identification of complex mixtures of PAHs in environmental samples. The separation and extraction of the individual component spectra of PAH mixtures affords valuable information about these hazardous compounds. Such information may allow for a detailed study of the means to remove their influence from the environment. The differences in the intensity contributions from a mixture of PAHs in a multicomponent system could be related to the differences in concentrations of the individual components and their respective quantum efficiencies. The problem is exacerbated by the fact that most solutions containing mixtures of PAHs display broad fluorescence spectral bands at room temperature, resulting in significant overlap and limited specificity for multicomponent analysis. This makes the success of multidimensional fluorescence measurements for complete spectral resolution of a complex multicomponent mixture dependent upon the degree of spectral overlap among the individual components and their fluorescence

emission spectra. In contrast, however, the problem of spectral resolution allows for a simple and convenient means for the incorporation of other useful chemical measurements in fluorimetric analysis.

The combination of multidimensional fluorescence analysis and quenching studies has allowed component resolution of PAHs complexed with  $\beta$ -cyclodextrin ( $\beta$ -CD). For example, upon the addition of iodide, the fluorescence intensity of fluanthrene and pyrene in aqueous solution is quenched to less than 10% of its original intensity. The quenching is dramatically reduced upon addition of  $\beta$ -cyclodextrin to a 1% *t*-butanol solution containing pyrene–fluanthrene. **Figure 3** illustrates the utility of a multidimensional fluorescence scheme in combination with cyclodextrin complexation to achieve resolution of a two-component mixture of pyrene and fluanthrene.

Many petroleum-based samples contain complex mixtures of PAHs, which are known or suspected carcinogens and mutagens. Multidimensional fluorescence analysis is suitable for the identification of fluorophores contained in oil samples. The basis of this technique is to employ a unique spectral fingerprint for the selective characterization and mapping of certain PAHs in the oil. Such a procedure is likely to provide a detection scheme for selective analysis of environmental samples for analytically important hazardous compounds. The primary goal will be to expand this technique to create a library containing

**Figure 3** Isometric plots of fluorescence showing the EEMs of (A) a pyrene–fluanthrene mixture in 1% *t*-butyl alcohol; (B) a pyrene–fluanthrene mixture in 1% *t*-butyl alcohol and 100 mmol L<sup>-1</sup> iodide; (C) a pyrene–fluanthrene mixture in 1% *t*-butyl alcohol, 100 mmol L<sup>-1</sup> iodide, and 1.5 mmol L<sup>-1</sup>  $\beta$ -CD; (D) a pyrene–fluanthrene mixture in 1% *t*-butyl alcohol, 100 mmol L<sup>-1</sup> iodide and 3.8 mmol L<sup>-1</sup>  $\gamma$ -CD. (Reprinted with permission from Nelson G, Neal SL, and Warner IM (1986) Resolution of mixtures by cyclodextrin complexation and multidimensional data analysis. *Spectroscopy* 3: 24–28.)

spectral fingerprints with specific characteristics unique to each individual oil sample. The added feature of this technique is that the identification of individual components is dependent on the relative concentration of each PAH in the oil sample. The identification of important emission bands is successfully accomplished by the use of contour plots. Thus, in areas of environmental pollution, fingerprinting techniques should be recognized as a screening method for PAH analysis.

The utility of multidimensional fluorescence is demonstrated using EEMs for comparative analysis in the determination of compounds that share a common source. This technique is effectively applied in characterization and extraction of important information from gasoline and motor oil samples. Multidimensional fluorescence of gasoline samples has definite potential importance in forensic applications. For example, it is suggested that this technique could provide the analyst with tentative evidence in a criminal or civil case by matching the fluorescence emission spectra from a suspect's car to that from the scene of a crime. In addition to forensic motor oil and gasoline identification, fingerprinting techniques have a greater application for determination of the effects of oil spills on marine life and the environment. The technique shows great potential in that it is precise and convenient for forensic and environmental analyses.

Another feature of multidimensional fluorescence is that it provides a good potential for a better spatial resolution, especially when using CCD detectors. The CCD detector is able to improve the detection of a fluorescent mixture of PAHs and provides a large dynamic range and reproducibility of spectral properties of the sample.

## Applications in Phytoplankton Analysis

The selectivity and specificity of multidimensional fluorescence measurements can be beneficial for the characterization and spectral fingerprinting of different classifications of marine phytoplankton or algae. Different and characteristic pigments in the algae produce spectral differences that may be used for the classification of different types of algae. Multidimensional fluorescence measurements are well suited for the spectral fingerprinting of phytoplankton since the entire visible region of the spectrum can be analyzed simultaneously. The individual pigments found in the algae are classified as either a type of chlorophyll, carotenoid, or phycobilin. The distribution of these pigments in the algae provides a unique distribution

between greens, blue-greens, and those that contain a carotenoid complex. By visually examining the EEMs of the different algae, it is possible to differentiate between species within a class of algae. The fingerprinting of algae has been accomplished using a portable multichannel fluorescence spectrometer (PMFS). The PMFS shows enhanced capabilities for rapidly acquiring and fingerprinting fluorescence emission spectra of algae over conventional fluorimeters. Multidimensional fluorescence analysis has the potential for indirect monitoring of the presence of pollutants in marine environments using algae as a bioindicator. This technique is especially suited for rapid measurement of algal fluorescence.

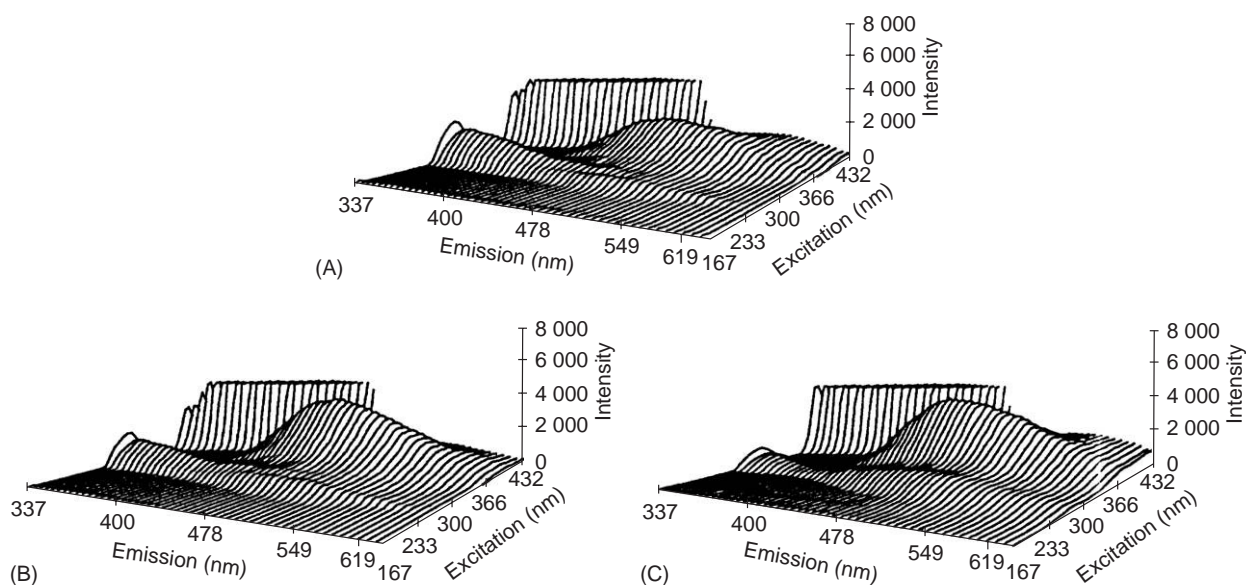

The versatility of multidimensional fluorescence techniques can be further improved by incorporating optical fibers into the instruments. Optical fibers offer the advantages of geometrical flexibility, environmental versatility, and small size and enable online monitoring of systems or detection of species in awkward or remote regions. In this approach, the optical fiber is placed directly in the sampling region, which precludes the need for sampling. The fluorescence is collected through the fiber and transferred to the detector via the optical fiber. Multidimensional fluorescence measurements for the analysis of marine phytoplankton in remote locations using fiber-optic-based sensing have been described previously. The presence of different characteristic pigments allows a remarkably simple classification of algae.

## Applications in Biological Fluid Analysis

Multidimensional fluorescence measurement is also very useful for applications that involve the separation and structural elucidation of potential therapeutic drugs. The capability for rapid acquisition of spectral data and enhanced detection limits achieved by use of fluorescence measurements is an important advantage for multidimensional fluorescence measurements. This detection is important for the screening of unknown compounds in complex mixtures, such as in the area of Pharmaceuticals. The utility of a video fluorimeter in this regard is demonstrated for the analysis of unused growth medium, typical cancer cell, and typical normal cell samples (Figure 4).

Investigation of complex biological samples, such as the analysis of bovine serum albumin, could be best achieved by employing the high resolving power of multidimensional fluorescence spectroscopy. An isometric projection will allow for a simultaneous observation of all the data points in each of the scans. In addition to a more pictorial representation of the

**Figure 4** Isometric projections of EEMs: (A) unused growth medium; (B) supernatant from noncancerous cell medium; (C) supernatant from cancerous cell medium. (Reprinted with permission from Rossi TM, Quarles JM, and Warner IM (1982) Analytical studies of fluorescent metabolites of cancer cells. *Analytical Letters* 15(B13): 1083–1098.)

experimental data, multidimensional fluorescence measurements are efficient, versatile, and provide enhanced information. Furthermore, in this field of biological and biochemical applications, multidimensional fluorescence accelerates the collection of important information on the spectral differentiation of the complexes formed when therapeutic drugs interact with their target cells on tissues in the body. This technique shows much improvement in the ability to quantify and check the purity of drugs and to select the optimal conditions for their analysis.

This technique also provides a better application of pattern recognition. Pattern recognition techniques have been used for the analysis of mixtures of fluorescent compounds with overlapping bands. The fluorescence contours of human sera have been explored as a new variant of pattern recognition methods in clinical chemistry. The rationale for this type of study is based on the fact that biomolecules are highly fluorescent when strongly bound to protein as compared to when free in solution. It is apparent that such an approach will provide the ability to achieve low limits of detection, which are critical, especially for pH-sensitive biological studies where pH change could have a profound influence on the resulting contour map. The limitation of pattern recognition is that the technique does not lead to analytically quantitative measurement of each individual component in the sample mixture. Thus, pattern recognition does not provide complete fluorescence spectral information about all of the individual components contributing to the total fluorescence of the multicomponent mixture.

It is clear that increased dimensionality of measurement effectively improves the resolution of overlapping fluorescence emission spectra. However, it should be emphasized that multidimensional fluorescence alone does not always result in complete resolution of spectrally overlapping fluorescence emission bands. In order to be able to successfully extract the most important information from the spectral data, the analyst should be able to observe and understand real changes as opposed to artifacts in the sample. These types of spectral changes are often clearly shown in the graphical or contour display of three-dimensional fluorescence spectra.

## General Applications

The selectivity of multidimensional fluorescence measurements, coupled with excellent detection limits provided by fluorescence techniques, will allow for fruitful investigations of a wide range of multicomponent mixtures. The information obtained from these types of measurements are valuable for the identification of individual components in complex mixtures and in the investigation and formulation of equilibrium binding models. It should be noted that in biological fluid systems, selective detection is extremely important in the final formulation of the equilibrium binding model and in the identification of the individual analyte.

The advent of multidimensional fluorescence measurements is also useful in the screening of inclusion complexes. Thus, the multidimensional

approach need not be limited to the identification and quantification of almost every analyte in the sample mixture. For example, in the case of an oil spill it is significant to examine the entire sample to produce a fingerprint for use in the identification of patterns relating to its classification. The goal of multidimensional fluorescence measurements is to enhance selectivity. Furthermore, the resolution and accuracy of this technique improve the sensitivity of the method. Despite severe spectral overlap, the results always indicate that multidimensional analysis is superior to conventional fluorimetric analysis.

## Introduction

Fluorescence spectrometry is a well-known method for quantitative analysis of various classes of molecules. Compared to absorption spectrometry it provides in general higher sensitivity and selectivity. However, conventional room-temperature fluorescence excitation and emission spectra are usually broad (e.g., 10 nm or more) and show no or hardly any fine structure. Obviously, its potential for qualitative analysis would be strongly extended if an increase in spectral resolution could be obtained, so that the vibrational fine structure of the spectra became visible (see **Figure 1**). This has been realized in high-resolution fluorescence spectroscopy, which has a sensitivity similar to that of conventional fluorescence spectroscopy and a selectivity comparable to that of infrared (IR) spectroscopy.

Why are conventional fluorescence spectra of molecules in liquid or solid solutions almost featureless?

First, it should be realized that for a particular analyte molecule the interaction with its surrounding cage strongly influences the energy distance between the electronic excited state ( $S_1$ ) and the electronic ground state ( $S_0$ ). In a solid, amorphous solution the specific cage conformation and thus the associated  $S_0$ – $S_1$  energy distance differs from molecule to molecule. In a fluid solution, the cage configurations also fluctuate strongly in time. Second, in fluids frequent inelastic collisions of dissolved molecules and solvent molecules occur, leading to considerable shortening of the excited-state lifetime of the analyte. Finally, there can be numerous vibronic (where vibrational and electronic states change simultaneously) fluorescence transitions, separated by relatively small energy distances, that will merge into featureless bands because they are all subject to the band-broadening processes mentioned above.

Lowering the temperature is a first step to enhance the spectral resolution. Although some resolution may be gained this way, in most cases cooling alone is not sufficient to obtain narrow-banded electronic emission spectra. As noted above, the sample will contain a large ensemble of molecules, each with a different solvent cage and a statistical distribution of

approach need not be limited to the identification and quantification of almost every analyte in the sample mixture. For example, in the case of an oil spill it is significant to examine the entire sample to produce a fingerprint for use in the identification of patterns relating to its classification. The goal of multidimensional fluorescence measurements is to enhance selectivity. Furthermore, the resolution and accuracy of this technique improve the sensitivity of the method. Despite severe spectral overlap, the results always indicate that multidimensional analysis is superior to conventional fluorimetric analysis.

## Introduction

Fluorescence spectrometry is a well-known method for quantitative analysis of various classes of molecules. Compared to absorption spectrometry it provides in general higher sensitivity and selectivity. However, conventional room-temperature fluorescence excitation and emission spectra are usually broad (e.g., 10 nm or more) and show no or hardly any fine structure. Obviously, its potential for qualitative analysis would be strongly extended if an increase in spectral resolution could be obtained, so that the vibrational fine structure of the spectra became visible (see **Figure 1**). This has been realized in high-resolution fluorescence spectroscopy, which has a sensitivity similar to that of conventional fluorescence spectroscopy and a selectivity comparable to that of infrared (IR) spectroscopy.

Why are conventional fluorescence spectra of molecules in liquid or solid solutions almost featureless?

First, it should be realized that for a particular analyte molecule the interaction with its surrounding cage strongly influences the energy distance between the electronic excited state ( $S_1$ ) and the electronic ground state ( $S_0$ ). In a solid, amorphous solution the specific cage conformation and thus the associated  $S_0$ – $S_1$  energy distance differs from molecule to molecule. In a fluid solution, the cage configurations also fluctuate strongly in time. Second, in fluids frequent inelastic collisions of dissolved molecules and solvent molecules occur, leading to considerable shortening of the excited-state lifetime of the analyte. Finally, there can be numerous vibronic (where vibrational and electronic states change simultaneously) fluorescence transitions, separated by relatively small energy distances, that will merge into featureless bands because they are all subject to the band-broadening processes mentioned above.

Lowering the temperature is a first step to enhance the spectral resolution. Although some resolution may be gained this way, in most cases cooling alone is not sufficient to obtain narrow-banded electronic emission spectra. As noted above, the sample will contain a large ensemble of molecules, each with a different solvent cage and a statistical distribution of

**Figure 1** Fluorescence of 1-methoxybenz[a]pyrene in *n*-octane at room temperature and at 10 K. Room temperature spectrum (upper line): concentration,  $2.5 \times 10^{-5} \text{ mol l}^{-1}$ ; bandpass, 0.8 nm. Shpol'skii spectrum (lower line): concentration,  $5 \times 10^{-6} \text{ mol l}^{-1}$ ; band pass, 0.15 nm. The spectra were recorded using otherwise the same experimental settings; lamp excitation at 295 nm.

transition energies is observed. In an amorphous frozen solution, the spectral bandwidths are in general of the same order of magnitude as measured in fluid media. In order to obtain sufficiently narrow fluorescence spectra the inhomogeneous broadening of the spectral bands has to be strongly reduced. This can be achieved in mixed crystal, matrix isolation, and Shpol'skii spectroscopy, solid-state techniques aimed at the creation of equal solute-solvent cage interactions for all the analyte molecules. They differ with respect to the type of matrix utilized, the manner in which the guest molecules are incorporated in the host, and the preparation of the sample.

Fluorescence line-narrowing (FLN) is another technique with which highly resolved fluorescence spectra can be obtained. The method is in principle more universally applicable and makes use of selective excitation, preferably with a laser. Only those analyte molecules that have a specific  $S_1-S_0$  energy difference exactly corresponding to that of the laser wavelength are selected. Ideally, in the solid-state matrix the population thus created remains conserved and will produce a highly resolved FLN spectrum.

In this article, we will concentrate on Shpol'skii spectroscopy (SS), matrix isolation (MI) spectroscopy in relation to SS, and FLN spectroscopy with emphasis on analytical applications. Mixed crystal spectroscopy will not be considered because virtually no analytical applications have been realized thus far. In this method the guest molecules have to be incorporated substitutionally in the host crystal without appreciable distortion of the crystal lattice. This means that the molecular geometries of guest and host are very critical and that the preparation of a good-quality mixed crystal is tedious. Finally, it is

noted that solid-state techniques are not the only techniques to achieve high resolution. In the past a lot of effort has been devoted to supersonic expansion fluorimetry: under favorable conditions analyte molecules seeded in supersonic jets can be considered as isolated and extremely cold, thus producing highly resolved fluorescence spectra. Very sharp spectra can be obtained, yielding information on vibrational and rotational transitions. However, the analytical potential of the technique seems limited since the detection limits achieved are relatively unfavorable. In this section, only solid-state techniques will be discussed.

## Principles

The principles of three cryogenic high-resolution fluorescence techniques will be outlined, namely MI spectroscopy, SS, and FLN spectroscopy.

### Matrix Isolation Spectroscopy

In this technique, originally developed in the 1950s to study transient (especially inorganic) species, the sample is vaporized and mixed with a large amount of an inert gas, the so-called matrix gas, generally in a molar ratio of  $10^4$ – $10^8$ . Next, the mixture is deposited on a cryogenic surface held at a temperature of 15 K or lower, which can easily be obtained with helium cryostats. Ideally, in this way the solute species are matrix isolated. Inert matrix gases originally used were the noble gases neon, argon, and xenon; later, especially for organic compounds, nitrogen and even *n*-alkanes and *n*-perfluoroalkanes were applied as matrix gas (see Figure 2). In the ideal situation the characteristics of these so-called low-temperature matrix-isolated solutions are the absence of solute aggregates, no diffusion of the solute molecules, no rearrangement of the matrix lattice, and minimal interaction between the matrix and the solute molecules. Considering these features, it is obvious that the MI technique appears very suitable for obtaining highly resolved spectra of organic compounds for quantification and qualitative analysis. However, especially if lamp excitation is used, the spectral resolution observed for organic compounds in conventional matrices of nitrogen and argon is often only slightly better than that obtained in glassy frozen solutions. Apparently, the reduction of inhomogeneous broadening in these examples is rather small. For this reason, lasers have been introduced to reduce the inhomogeneous broadening by the FLN effect (see below) and 'Shpol'skii-like' matrix gases such as *n*-alkanes and *n*-perfluoroalkanes have been applied.

In order to utilize MI for quantitative analysis an internal standard should be included to compensate for incomplete recovery, i.e., nonquantitative analyte deposition. Important criteria for the internal standard are that its fluorescent spectrum should not overlap with the spectra of the analyte(s), it should sublime at approximately the same temperature as the analyte(s), and the excitation wavelength should be the same as for the analyte(s).

### Shpol'skii Spectroscopy

In 1952, Shpol'skii, a Soviet scientist, reported the observation of narrow spectral lines in the emission spectra of aromatic molecules dissolved in *n*-alkanes (*n*-C5 to *n*-C12), measured at low temperatures ( $T \leq 77$  K). By freezing the *n*-alkanes a polycrystalline

rather than a glassy solid matrix is obtained, in which the analyte molecules are trapped at the point of solidification. The compatibility of guest and host geometry is less stringent than in mixed crystals. In the polycrystalline matrix a reduction in the inhomogeneity of the environment of the guest molecules is achieved, and at temperatures below 20 K narrow spectral bands with bandwidths  $\sim 0.1$  nm may be observed. The Shpol'skii spectra often display several identical spectra that are displaced with respect to each other over a few nanometers (see the doublet spectrum in Figure 1). This so-called site structure is due to subpopulations of chemically identical molecules that are differently oriented inside the crystalline matrix, and is strongly dependent on the matrix used. This phenomenon is unfavorable in terms of the sensitivity of the method, but sometimes profitable for identification purposes.

As the Shpol'skii effect is induced by the matrix, both the absorption and emission spectra measured at low temperatures will be narrow-banded. This holds especially for the long wavelengths (i.e.,  $S_0$ - $S_1$  absorption); shorter-wavelength bands are broadened as a result of the lifetimes of the higher excited states (the Heisenberg uncertainty principle). Thus, using a laser as excitation source (laser-excited Shpol'skii spectroscopy, LESS) an enhancement of the selectivity can be realized. Figure 3 shows a three-dimensional excitation emission spectrum of pyrene in *n*-octane. Emission spectra were continuously recorded as the laser was tuned through the 0-0 transition. Pyrene- $d_{10}$  was also present in the mixture but, although its excitation wavelength is shifted over only 1 nm, it is completely invisible, as the laser line does not match it exactly. It is clear that we have here a powerful tool for increasing the emission of a particular analyte and at the same time reducing interferences from other compounds.

A serious drawback of SS is that the choice of matrices is restricted and that for many analytes

**Figure 2** Matrix isolation spectra for a six-component mixture of polycyclic aromatic hydrocarbons (PAHs); lamp excitation at 313 nm. P=pyrene, C=chrysene, BbF=benzo[*b*]fluorene, T=triphenylene, Ph=phenanthrene, BaF=benzo[*a*]fluorene.

**Figure 3** Excitation – emission plot of pyrene ( $5 \times 10^{-7}$  mol  $l^{-1}$  in *n*-octane) at different laser excitation wavelengths.

there may not be suitable solvents to obtain narrow-line spectra. Further, the shape of the spectra is influenced by experimental parameters, such as the cooling rate, the thermal treatment, the concentration of the sample, the solvents chosen, and the sample temperature during the spectroscopic measurement (preferably 20 K or lower). Fortunately, many large planar molecules yield Shpol'skii spectra that are not very sensitive to the thermal history of the sample. Furthermore, several types of internal standards can be employed to correct for such effects (see below).

### Fluorescence Line-Narrowing Spectroscopy

In this type of spectroscopy, first applied in 1972 by Personov, a reduction of the inhomogeneous broadening is realized by optical selection of the molecules that are excited. An excitation source is used with a spectral bandwidth that is considerably narrower than the inhomogeneous bandwidth of the molecules that are probed. With such a selective excitation process a well-defined subset of excited molecules is created; only molecules with an energy difference between ground state and excited state that is exactly equal to the energy of the exciting photons are excited (see Figure 4). It is clear that in this case lasers are the most appropriate excitation source. If during the lifetime of the excited state no spectral diffusion can occur, only this well-defined subset or 'isochromat' will give fluorescence. This means that the measurements have to be performed at low temperatures, at least at 20 K or lower. Excitation may occur in the 0-0 electronic transition (i.e., from the lowest vibrational state in  $S_0$  to the lowest

vibrational state in  $S_1$ ), or into vibrational states of  $S_1$ . The latter approach may lead to multiplets, as several vibronic bands are probed simultaneously and decay to their corresponding purely electronic states, thus creating several well-defined subsets of excited molecules. These multiplets have been used for identification purposes of closely related isomers. Usually, excitation into high vibrational states more than  $1600\text{ cm}^{-1}$  above the 0-0 transition or into higher electronic states does not lead to good line-narrowed spectra.

Although FLN has been applied in various solvents, there is no total freedom of solvent choice. The main prerequisite is that there is no strong interaction between the matrix and guest molecules. Strong electron-phonon coupling (phonons are vibrational motions throughout the matrix) prohibits the observation of line narrowing in the spectrum.

High analyte concentrations should be avoided since intermolecular energy transfer can lead to line broadening. The same holds for local heating of the matrix, which may lead to site interconversion due to diffusion of the matrix and to a loss of the line-narrowing effect. Finally, the occurrence of 'hole-burning' effects in FLN spectra should be mentioned. Two types are discerned, i.e., photochemical and nonphotochemical hole burning. The former is due to photochemical reactions of the excited molecules. In nonphotochemical hole burning, reorientation of guest molecules in the excited state with respect to their solvent cage plays a role. Both effects result in a gradual decrease in the ground-state population that can be selectively excited by the laser and hence in a reduction of the narrow-line intensities in the spectrum upon prolonged irradiation.

Because of the broader choice in solvents compared to SS, the applicability of FLN is much wider. On the other hand, the sensitivity of FLN is in principle not as high as that of LESS since, due to the optical selection, only a fraction of the analyte molecules is detected.

### Instrumentation

To date no complete, dedicated experimental setups are commercially available; only a few research groups have been able to apply the low-temperature high-resolution techniques. The instrumentation is regarded as exotic in analytical laboratories: lasers, cryogenic cooling apparatus, and high-resolution detection devices are not common equipment.

In this section, some instrumental aspects that are relevant for the achievement of highly resolved fluorescence spectra will be discussed. Particular

**Figure 4** Fluorescence emission spectra of 20 ng pyrene on a C-18 modified silica HPTLC plate. Upper spectrum: lamp excitation at room temperature. Lower spectrum: laser excitation at 363.5 nm;  $T = 10\text{ K}$ .

attention will be paid to excitation, cooling, and detection systems.

### Excitation

In the past, the most frequently used excitation sources for matrix-induced line-narrowing (as in SS) were conventional light sources such as xenon and mercury lamps in combination with a monochromator of sufficient spectral resolving power. Obviously, these sources are inappropriate if selective excitation is essential and bandwidths down to  $\sim 0.2$  nm are required. These can only be realized by using narrow monochromator slits, with, as a consequence, extremely low light intensities. The availability of robust and user-friendly laser systems has had a strong impact on high-resolution fluorescence spectroscopy. Considerable improvements in sensitivity and selectivity have been achieved by using a tunable laser instead of a lamp (LESS), since not only the fluorescence emission but also the long-wavelength part of the excitation spectra is composed of narrow lines. For FLN spectroscopy laser excitation is essential.

Within this context it is appropriate to discuss the impact of lasers in more general terms. In general, the exchange of classical light sources for lasers has greatly extended the analytical potential of molecular fluorescence techniques. Some inherent features of lasers are of extreme importance. First, the directionality of the radiation, which not only enables collimation down to spot sizes of  $1\text{ }\mu\text{m}$  but also guarantees a sufficiently high sample irradiance to perform analysis far away from the light source (as in remote sensing). The inherent high monochromaticity of lasers is of only limited use for the analysis of fluid or frozen solutions with broadband excitation spectra, since only a small fraction of analytes would have adequate spectral overlap with the laser line. In contrast it is very important, even essential, in FLN and LESS. It must be realized that the fluorescence signal of the analyte increases with the irradiance (power of the laser in watts per unit area of the sample), but that excessive irradiances can cause problems, e.g., detector cell damage due to plasma formation, saturation effects, and photochemical decomposition of the fluorophores. These effects most often occur with pulsed lasers with high peak powers.

Finally, the ability to produce pulsed laser radiation with a short lifetime on the fluorescence timescale opens up the possibility of applying time-resolved detection principles to improve the signal-to-background ratio (see Figure 5).

For laser application in analytical spectroscopy it is important that laser lines are available over a large wavelength region. In particular, laser output in the

**Figure 5** Shpol'skii fluorescence spectra of pyrene in crude bird extract, *n*-octane at 28 K; laser excitation 372.10 nm. Upper spectrum: without time resolution. Lower spectrum: with time-resolved detection; delay = 50 ns.

ultraviolet (UV) is necessary for the ability to detect all types of compounds. UV laser radiation can be obtained by means of dye lasers or nonlinear techniques such as frequency doubling. Nevertheless, laser wavelength selection is still far less convenient than wavelength selection in a conventional scanning fluorimeter.

### Cooling Systems

For the high-resolution fluorescence techniques described here, samples are measured under cryogenic conditions. Cooling of the sample to 10–30 K can be performed in different ways: by means of a bath cryostat, a closed-cycle helium refrigerator, or a flow-through cryostat. In a bath cryostat the sample is immersed in liquid helium so that a temperature of 4.2 K can be achieved almost instantaneously. Disadvantages are the consumption of liquid helium and the presence of boiling helium in the optical pathways of most cryostat designs, which may disturb the measurements.

A very convenient cooling apparatus is the closed-cycle helium refrigerator, in which repeated compression and expansion of gaseous helium takes place. The sample is placed in a vacuum and attached

to a cold finger in contact with the cryogenic medium. Good thermal contact between the sample holder and the cold tip is crucial. Nowadays, temperatures as low as 4 K can be achieved. This apparatus has the advantages that it requires only line electrical power and that no expensive liquid helium is consumed.

The helium flow-through cryostat uses liquid helium that is pumped from a container and sprayed onto the bottom of the cold tip. In this case, temperatures of 3.5 K can be reached. The cooling process takes a long time (typically 1 h), both with the closed-cycle helium refrigerator and the flow-through cryostat. Several samples should preferably be cooled simultaneously.

### Detection

High-quality (emission) monochromators are necessary to disperse the emitted light and record narrow-banded spectra. Particularly if there is only a small difference between excitation and emission wavelengths, the interference from scattered excitation light (likely to be strong in the case of solid samples) has to be minimized, so that the use of a triple monochromator is preferred. In many of the earlier setups, detection was done with a (cooled) photomultiplier tube (PMT), measuring the averaged photocurrent, coupled to a lock-in amplifier. Low-level light intensities can be detected more effectively with a fast PMT, followed by a photon counting system. However, in order to record a full high-resolution spectrum the scanning process may take very long.

In recent years, multichannel detectors have become more and more popular, especially intensified linear diode arrays and CCD cameras. These devices offer a sensitivity similar to that of PMTs, while a complete spectrum can be recorded simultaneously. Apart from the substantial reduction in measurement time, another advantage is the fact that in the case of signal fluctuations (e.g., due to photodegradation, hole burning) all peaks in the spectrum are equally affected. For time-resolved detection a pulsed excitation source and a fast gateable intensified camera can be used.

### Applications

In this section, some representative examples of analytical applications are presented. It is not intended to give a complete overview.

#### Matrix Isolation

Currently, MI sample preparation techniques are used mainly in combination with vibrational

spectroscopy, especially Fourier transform IR, while fluorescence spectroscopy is involved to a minor degree. Fluorescence studies of organic compounds have been devoted to unstable, reactive species. Applications in analytical chemistry have been published mainly by Wehry's group, focusing especially on polycyclic aromatic hydrocarbons (PAHs).

An example is the analysis of very complex samples such as chromatographic fractions of coking plant wastewater. **Figure 6** shows the MI high-resolution fluorescence spectra obtained by applying broadband excitation by a xenon-mercury lamp at 15 K. In the upper spectrum nitrogen is the matrix gas; in the lower one *n*-heptane is utilized and a 'Shpol'skii-type' spectrum is obtained. The selectivity of the MI technique is obvious: even under lamp excitation six PAHs could be simultaneously identified in the complex sample.

Within the context of the development of coupled techniques the combination of gas chromatography and MI (GC-MI) utilizing fluorescence spectroscopy for detection and identification is interesting. Until recently this development was hampered by the long scan times required to obtain high-resolution fluorescence spectra of deposited species. Optical multi-channel detection can now be invoked to tackle this problem.

**Figure 6** Lamp-excited MI spectra of chromatographic fraction of coking plant wastewater, in nitrogen (upper spectrum) and *n*-heptane (lower spectrum) matrices at 15 K. BbF = benzo[*b*]fluororene, C = chrysene, P = pyrene, BkF = benzo[*k*]fluoranthene, BaP = benzo[*a*]pyrene, Pe = perylene, U = unidentified.

Finally, it is noted that the MI technique is not exclusively applicable to analytes exhibiting native fluorescence. In the literature much attention has been paid to laser-photolytic gas-phase fragmentation reactions producing fragments that can be detected by means of fluorescence. Instead of fluorescence, molecular phosphorescence has also been utilized. This is illustrated in **Figure 7**, showing laser-induced phosphorescence spectra of 2-chloronaphthalene. In this experiment, the appropriate matrix was composed of naphthalene, the parent molecule. In fact, such a matrix will behave like a mixed crystal, which explains the strong improvement of the spectrum quality on going from *n*-pentane to naphthalene. The approach enables high selectivity for halogenated naphthalenes in general.

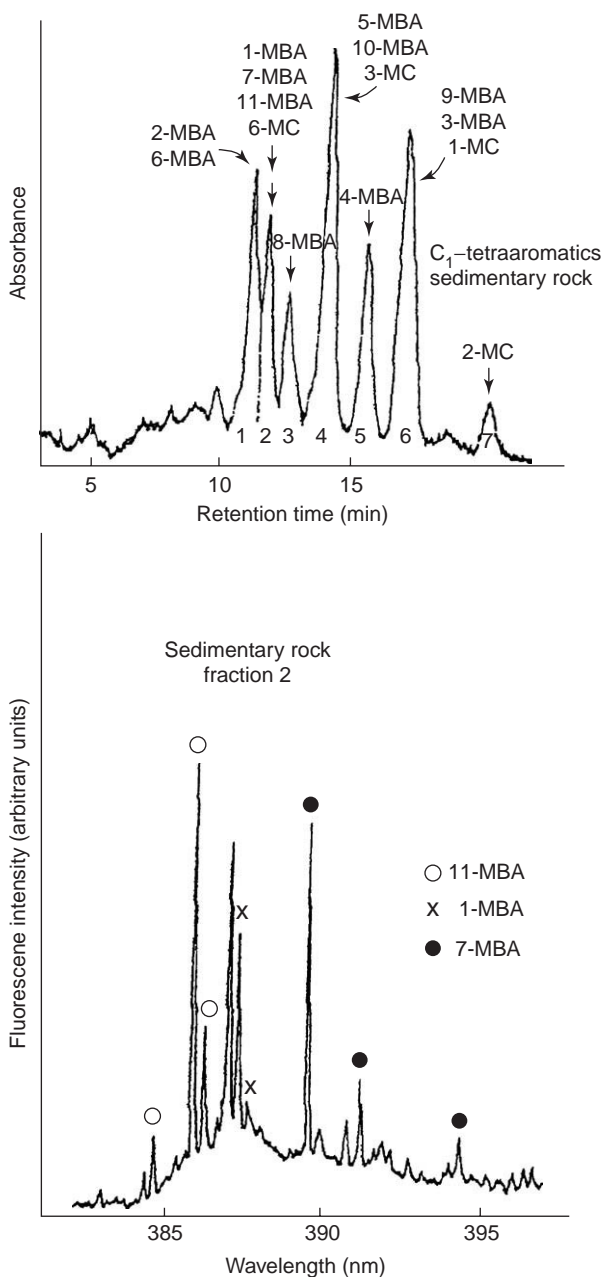

### Shpol'skii Spectroscopy

To date hundreds of papers have been published dealing with the application of SS in chemical analysis, often devoted to PAHs in environmental matrices (e.g., air, river, and marine sediments, coal and oils). The main object has been qualitative analysis, which is not surprising in view of the detailed vibrational structures exhibited by the spectra in combination with the characteristic wavelength of the

electronic origin in a specific matrix. (It is to be noted that the latter feature is not provided by FLN since the origin of FLN spectra is largely determined by the laser wavelength applied.) The selectivity of SS has been demonstrated by lamp- and laser-excited SS of structurally related methyl isomers of PAHs, using both fluorescence and phosphorescence measurements. As an example, **Figure 8** shows the

**Figure 7** Laser-induced phosphorescence spectra of 2-chloronaphthalene, vapor-deposited in an *n*-pentane matrix (upper; 320 nm exc.) and in a naphthalene matrix (lower; 324 nm exc.).

**Figure 8** Top frame: reversed-phase LC analysis of a tetra-aromatic fraction from a sedimentary rock with tentative assignment of methylbenz[a]anthracenes (MBA). Bottom frame: Shpol'skii fluorescence spectra ( $\lambda_{\text{ex}} = 294 \text{ nm}$ ) showing unambiguously the presence of 11-MBA, and 7-MBA.

**Figure 9** Shpol'skii spectra of pyrene (—) and 1-fluoropyrene (·····) under different experimental conditions: (A) *n*-hexane matrix, slow cryocooling; (B) *n*-hexane matrix, fast precooling; (C) *n*-octane matrix, slow cryocooling; (D) *n*-octane matrix, fast precooling. Temperature, 11 K; analyte concentration,  $1 \mu\text{mol l}^{-1}$ ; lamp excitation at 338 nm.

identification of isomers of the mutagen methylbenz[*a*]anthracene (MBA) in a chromatographic fraction from a sedimentary rock.

Quantitative analysis by SS requires the use of an internal standard or a standard addition procedure in combination with an internal standard. This is necessary in view of irreproducibilities in sample preparation (including the cooling procedure) and optical alignment. Deuterated analogs of the analytes that show small though detectable spectroscopic shifts and have identical chemical behavior have proved very useful; in general, reproducibilities better than 10% can be realized. In recent years, an alternative set of internal standards were synthesized. Mono-fluorinated PAHs were found to yield high-quality Shpol'skii spectra (see **Figure 9**) and proved to be very useful as internal standards to correct for differences in alignment and thermal history.

With SS (and especially with LESS) extremely low detection limits can be achieved. To quote an example, for the highly fluorescent PAH benzo[*a*]pyrene in a 'synthetic' solution in *n*-octane at 10 K and using lamp excitation a detection limit of  $0.075 \text{ ng ml}^{-1}$  has been published; with laser excitation this was improved to  $0.0012 \text{ ng ml}^{-1}$ .

It is emphasized that, owing to the inherent selectivity of (LE)SS, sample cleanup procedures can often be minimized. An important example is the analysis in a crude river sediment extract of ultralow traces of dibenzo[*a,l*]pyrene, the most carcinogenic PAH known to man. Another interesting application is the identification and quantification of PAH metabolites in samples for biological monitoring. Although SS is not appropriate for highly polar compounds it can be applied to monohydroxy PAHs.

**Figure 10** Shpol'skii spectrum of methylated bile extract from fish from Wadden Sea mesocosm (least polluted control group). Site-selective laser excitation at 418.36 nm; IS (internal standard) = perylene- $d_{12}$ .

An important improvement of sensitivity was obtained by methylation of the hydroxy groups. As a result even in the bile of fish caught in relatively clean areas (as the Wadden Sea) BaP metabolites could be measured and quantified; this is illustrated in **Figure 10**, showing a LESS spectrum utilizing selective excitation and time-resolved detection. A similar procedure has been applied to determine 3-hydroxybenzo[*a*]pyrene in the urine of coke oven workers.

An interesting recent example is the use of Shpol'skii matrices to study ultrafast phenomena. The excited state proton transfer reaction in 3-hydroxyflavone could be calculated from the (relatively) broad bands in the Shpol'skii excitation spectrum, using the Heisenberg uncertainty principle.

## Fluorescence Line-Narrowing

Early reports on analytical applications of FLN were devoted to PAHs in environmental samples such as cigarette tar, soot, solvent-refined coal, and gasoline. For this type of problem LESS would be the (more appropriate) alternative, provided that the analytes can be brought into *n*-alkane solvents. Such an alternative is not available for the study of polar PAH metabolites (the activated forms of PAHs playing a suspected role in carcinogenesis) and their adducts with DNA, as they are poorly soluble in alkanes. Elucidation of their detailed structures is crucial to acquire insight into the mechanism of adduct formation and DNA damage. As shown by Small, Jankowiak, and co-workers, FLN can be of significant help, especially when adducts isomers with different stereochemistries need to be distinguished. **Figure 11** shows the FLN spectra of four different benzo[*a*]pyrene-DNA adducts in short pieces of synthetic double-stranded DNA. *cis* and *trans* adducts can be distinguished based on different vibrational frequencies, while the (+) and (−) stereochemistries can only be distinguished due to the different modes of embedding in the DNA helix. Since the FLN spectra are very sensitive to the nature of the surrounding microenvironment, the technique can also be used to study the interactions inside a receptor site or inside an antibody.

An interesting recent finding is that FLN is applicable to analytes on various types of thin-layer chromatographic (TLC) plates, after cooling the plate to 10–20 K. This enables the application of FLN

**Figure 11** FLN spectra of *anti*-BPDE-N<sup>2</sup>-dG adducts of different stereochemistries in duplex oligonucleotides. Curve A: (+)-*trans* adduct; curve B: (−)-*trans* adduct; curve C: (+)-*cis* adduct; curve D: (−)-*cis* adduct.  $\lambda_{\text{ex}} = 369.48$  nm. identification after TLC separation. Even more importantly, the combination with liquid chromatography (LC) is possible, since LC and TLC can be coupled successfully: the effluent from the LC column is deposited on a TLC plate moving with a constant speed so that an 'immobilized' chromatogram is obtained. Efficient eluent elimination and conservation of chromatographic integrity during the deposition process are crucial. Another promising approach is the online coupling of FLN and capillary electrophoresis. This is done by freezing the separated compounds inside the capillary to 4K and recording FLN spectra of the separate analyte zones (see Figure 12).

## Introduction

Fluorimetry has experienced an explosive growth since the early 1980s, much of which has been driven by the use of fluorescence as a noninvasive technique for biology and biochemistry. Fluorescence techniques are widely used to quantify molecular parameters of different chemical, biochemical, and biological processes because of their inherent sensitivity, specificity and temporal resolution. In fact, the luminescence lifetime is an important characteristic of a fluorescent molecule and its environment. Many intra- and intermolecular processes are able to modulate the molecule emission which cannot be investigated by steady-state fluorescence measurements. For example, rotational diffusion,

resonance-energy transfer, or dynamic quenching occur on the same timescale as the fluorescence decay. Lifetime measurements reveal dynamic information on the nanosecond timescale that is useful in fundamental studies of quenching and energy transfer and can be used in analytical methodologies to enhance selectivity and/or to perform multicomponent determinations. For example, fluorescence quenching may occur due to a ground state reaction or an excited state reaction. Only by measuring the fluorescence lifetime may one determine which process causes the quenching.

There are several experimental approaches to obtain lifetime data. The primary objective of these approaches is to obtain data representing the time dependence of the decay of the luminescence. For a single component sample in which the excited state decays by first-order processes the radiative fluorescence lifetime  $\tau_r$  represents the time the fluorophore remains on average in the excited state, before emission takes place. If there are  $N$  molecules in the excited state, the decrease  $dN$  of molecules that revert

identification after TLC separation. Even more importantly, the combination with liquid chromatography (LC) is possible, since LC and TLC can be coupled successfully: the effluent from the LC column is deposited on a TLC plate moving with a constant speed so that an 'immobilized' chromatogram is obtained. Efficient eluent elimination and conservation of chromatographic integrity during the deposition process are crucial. Another promising approach is the online coupling of FLN and capillary electrophoresis. This is done by freezing the separated compounds inside the capillary to 4 K and recording FLN spectra of the separate analyte zones (see Figure 12).

## Introduction

Fluorimetry has experienced an explosive growth since the early 1980s, much of which has been driven by the use of fluorescence as a noninvasive technique for biology and biochemistry. Fluorescence techniques are widely used to quantify molecular parameters of different chemical, biochemical, and biological processes because of their inherent sensitivity, specificity and temporal resolution. In fact, the luminescence lifetime is an important characteristic of a fluorescent molecule and its environment. Many intra- and intermolecular processes are able to modulate the molecule emission which cannot be investigated by steady-state fluorescence measurements. For example, rotational diffusion,

resonance-energy transfer, or dynamic quenching occur on the same timescale as the fluorescence decay. Lifetime measurements reveal dynamic information on the nanosecond timescale that is useful in fundamental studies of quenching and energy transfer and can be used in analytical methodologies to enhance selectivity and/or to perform multicomponent determinations. For example, fluorescence quenching may occur due to a ground state reaction or an excited state reaction. Only by measuring the fluorescence lifetime may one determine which process causes the quenching.

There are several experimental approaches to obtain lifetime data. The primary objective of these approaches is to obtain data representing the time dependence of the decay of the luminescence. For a single component sample in which the excited state decays by first-order processes the radiative fluorescence lifetime  $\tau_r$  represents the time the fluorophore remains on average in the excited state, before emission takes place. If there are  $N$  molecules in the excited state, the decrease  $dN$  of molecules that revert

to the ground state in a given interval of time,  $dt$ , is expressed by the relation

$$\frac{-dN}{dt} = k_f N \quad [1]$$

where  $k_f$  is the fluorescence constant rate.

The number of excited molecules therefore decreases exponentially with time:

$$N(t) = -N_0 \exp(-k_f t) \quad [2]$$

The time after which the number of excited molecules decreases from  $N_0$  to  $N_0/e$  is called the fluorescence lifetime. Taking into account the dependence of the luminescence signal on analyte concentration, the above equation can be expressed as

$$I(t) = I_0 \exp(-k_f t) \quad [3]$$

where  $I(t)$  is the luminescence signal after time  $t$  and  $I_0$  is the initial luminescence signal. If all the quanta of energy are lost as fluorescence, the fluorescence lifetime is given by the reciprocal fluorescence transition rate

$$\tau_f = \frac{1}{k_f} \quad [4]$$

In contrast to this radiation or intrinsic lifetime, the real lifetime,  $\tau_f$ , includes the nonradiative deactivation processes:

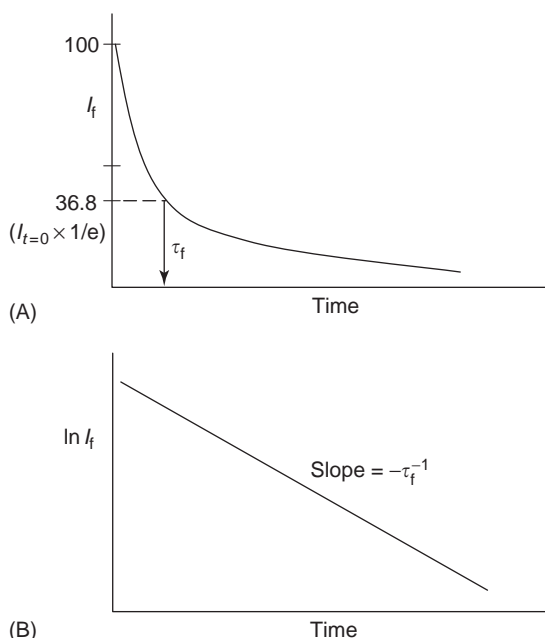

$$\tau_f = \frac{1}{k} = \frac{1}{k_f + k_{ISC} + k_Q} \quad [5]$$

The numerical value of  $\tau_f$  can be found from a plot of fluorescence intensity versus time, following termination of excitation (see **Figure 1A**).  $\tau_f$  is the time at which the intensity has decreased to  $1/e$  (36.8%) of its initial value. It is important to remember that fluorescence lifetime is an average time for a molecule to remain in the excited state before emitting a photon. Each individual molecule emits randomly after excitation. Many excited molecules will fluoresce before the average lifetime while some will also do long after the average lifetime.

Before the availability of laboratory computers, lifetimes were commonly determined by graphical procedures, for example, by taking the natural logarithm of both sides of eqn [3], we obtain

$$\ln I(t) = \ln I_0 - t/\tau_f \quad [6]$$

The negative reciprocal of the slope of a semilogarithmic plot of  $I(t)$  versus  $t$  yields the lifetime (see **Figure 1B**). This method assumes that the luminescence signal decays to zero for long times (background signals are supposed to be negligible). Other data-treatment approaches are available to extract the lifetime information and to compensate for residual background signal. For example, the natural

**Figure 1** (A) Hypothetical decay of fluorescence from an electronically excited state. (B) Logarithmic slope method to determine fluorescence lifetime.

logarithm of the difference in the luminescence signal between pairs of data points along the decay curve, evenly time-spaced, is plotted versus time (Guggenheim method). The lifetime is obtained from the negative reciprocal of the slope.

Although the calculated lifetime may have little physical meaning, for nonexponential decay and for multicomponent mixtures, the decay curve can be fitted to a weighted sum of exponential terms to obtain the lifetime of each component:

$$I(t) = \sum_{i=1}^n \alpha_i \exp(-t/\tau_i) \quad [7]$$

where  $\alpha_i$  is the pre-exponential factor denoting the fractional contribution to the total time-resolved decay of the component with lifetime  $\tau_i$ .

## Time-Domain Lifetime Measurements

Time-resolved fluorescence measurements are performed in two functionally equivalent ways: time domain and frequency domain. In time-domain or pulse-excitation fluorimetry, the fluorophore is excited with a short-duration pulse of light. The resulting fluorescence emission decay signal after the excitation pulse is captured with a fast recorder and the decay time is calculated from the slope of a plot of  $\log I(t)$  versus  $t$ . As the fluorescence species decay involves a process that occurs in a few nanoseconds,

the width of the pulse should be as short as possible and it is preferably to be shorter than the decay time of the analyte. If the excitation pulse width ( $t_p$ ) is shorter than the luminescence lifetime ( $\tau_f$ ), an exponential decay of the luminescence is observed. With nanosecond excitation pulse widths, the decay curve represents a convolution of the source and fluorescence decay, as illustrated in **Figure 2**. In this case, the following equation applies:

$$I_f(t) = \int_0^t I_r(t') I_f(t - t') dt' \quad [8]$$

where  $I_r(t')$  is the reference signal related to the time profile of the excitation pulse,  $I_f(t)$  is the measured decay curve and  $t'$  is a dummy integration variable ( $t > t'$ ). The term  $(t - t')$  indicates that the impulse response is started at  $t = t'$  and it is supposed that no emission is observed before excitation ( $t < t'$ ). The true fluorescence decay curve may be extracted from the experimental decay curve by deconvolution methods, so that the convolution integral is solved for  $I_f(t)$ . Most use least-squares methods in concert with an iterative reconvolution scheme. In this approach, one picks a test model (eqn [7]). The convolution integral (eqn [8]) is then calculated on the basis of an initial set of  $\alpha_i$  and  $\tau_i$  values and the measured instrument response function. The calculated response ( $C(t)$ ) is compared with the observed data ( $I_f(t)$ ) and the  $\alpha_i$  and  $\tau_i$  terms adjusted until a best fit is obtained. The quality of the fit is judged by chi-square ( $\chi^2$ ) test

$$\chi^2 = \sum_{j=1}^{np} W_j [I_f(t) - C(t)]^2 \quad [9]$$

where np is the number of data points in the decay file and  $W_j$  is a weighting factor. These mathematical analyses have two inherent drawbacks: (1) any gain shift or any drift in the instrumentation is reflected in the data as changes in the intensity of light, distorting the true nature of the data; and (2) any electrical

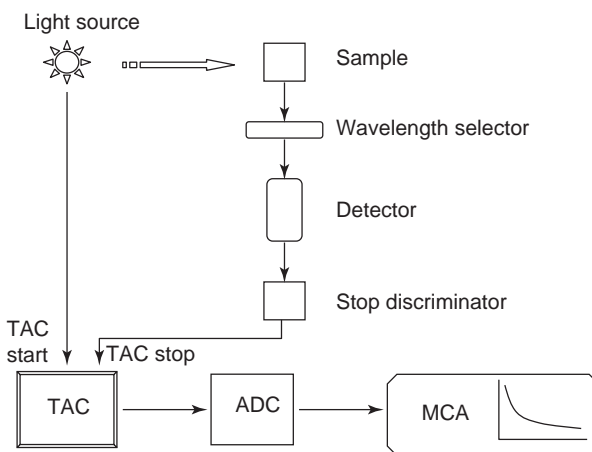

**Figure 2** Source and luminescence decay curves: 1, source time profile; 2, fluorescence decay curve; 3, true fluorescence decay curve. Assuming  $t_p \approx \tau_f$ , the initial part of the decay curve is distorted.

noise present in the instrumentation gets added to the signal, again distorting the data.

At present almost all time-domain measurements are performed using time-correlated single photon counting (TCSPC), an alternative analytical technique based on the ability to detect and count individual quanta, or photons, of light. The basics of single photon counting (SPC) can be understood by considering a block diagram of the instrumentation used (**Figure 3**). The light source delivers the excitation energy required to make the sample fluoresce. A pulsed light source, which generates an excitation pulse train, stimulates absorption of the sample molecule at repetition rates in the several kilohertz to several megahertz range, depending on the light source. Every time the light source sends a pulse of excitation energy, it also sends a start signal to the time-to-amplitude converter (TAC), a unit that measures the time elapsed from the start of the excitation pulse until a photon is detected. The sample is repetitively excited and each pulse is optically monitored by a detector, which is usually a high-speed photodiode or photomultiplier. The detector must have a very narrow entrance slit to ensure that only a single photon of light per 100 source pulses enters and is detected. For each photon collected, the photomultiplier generates an amplified signal which is sent to the stop discriminator, along with the signal due to the inherent photomultiplier noise (additive dark current).

The stop discriminator is an important element of the technique as it allows SPC to be essentially insensitive to the noise and drift problems which limit the analog approaches of light analysis. Basically, a discriminator is designed to differentiate between levels of electrical signals. For instance, if the input

**Figure 3** Basic components of a time-correlated single-photon counting system.

signal to the discriminator is below a specified threshold level, it produces an average output of zero; an input signal greater than the specified threshold level is recognized, thus producing an output pulse. By setting the discriminator level greater than the background signal noise but lower than the noise plus signal level, it is possible to eliminate noise and drift on the experiment.

The TAC may be considered as a stopwatch: the light source provides the start signal and the stop discriminator the stop timing. When the TAC receives the stop signal, it outputs a voltage pulse with an amplitude proportional to the elapsed time between starting and stopping. The events are collected in a memory location with an address proportional to the detection time. Thus, for one photon detected, we can have an accurate representation of just how long it has been since the sample was excited. A multichannel pulse height analyzer (MCA) converts the TAC voltage output to a time channel using an analog-to-digital converter (ADC). This process, which takes only a few microseconds from start to finish, is repeated until collecting more than 10 000 counts in the peak channel. Summing over many pulses, the MCA builds up a probability histogram of counts versus time channels, which represents the fluorescence decay of the sample (see Figure 4).

As was mentioned earlier, there can be no more than one photon detected per 50–100 source pulses. Electronics for SPC only allows detection of the first arriving photon. Once this photon is detected, the dead time in the electronics prevents detection of another photon resulting from the same excitation pulse. The apparent decay time becomes shorter as the number of arriving photons increases because the TAC is stopped by the first arriving photon. The pulse pileup problem is being solved to some extent by the development of dedicated electronic detection

systems and multiplexing methods for detection of multiple photons.

The time-resolved mode of measuring fluorescence lifetime is a digital or photon counting method that shows good signal-to-noise ratio. Advantages of time correlated SPC include a high dynamic range and the measured decay profile is independent of fluctuations in the excitation pulse intensity. Additionally, single photon detection theory is based upon well-documented statistics for which the precision, data weights, goodness-of-fit, and other parameters can be easily calculated.

## Time-Correlated Single Photon Counting Instrumentation

The main criterion for determining the overall system performance of the TCSPC system is the timing resolution and the sensitivity of the device. These characteristics vary from system to system and are largely based on the performance of the individual components. A schematic diagram of a simple TCSPC setup is shown in Figure 5. The instrumentation can be divided into three main groups of components:

1. the pulsed excitation source;
2. optical spectrometer components (lenses, monochromators, etc.); and
3. single-photon detector and timing electronics (discriminators, TAC, MCA).

### Light Sources

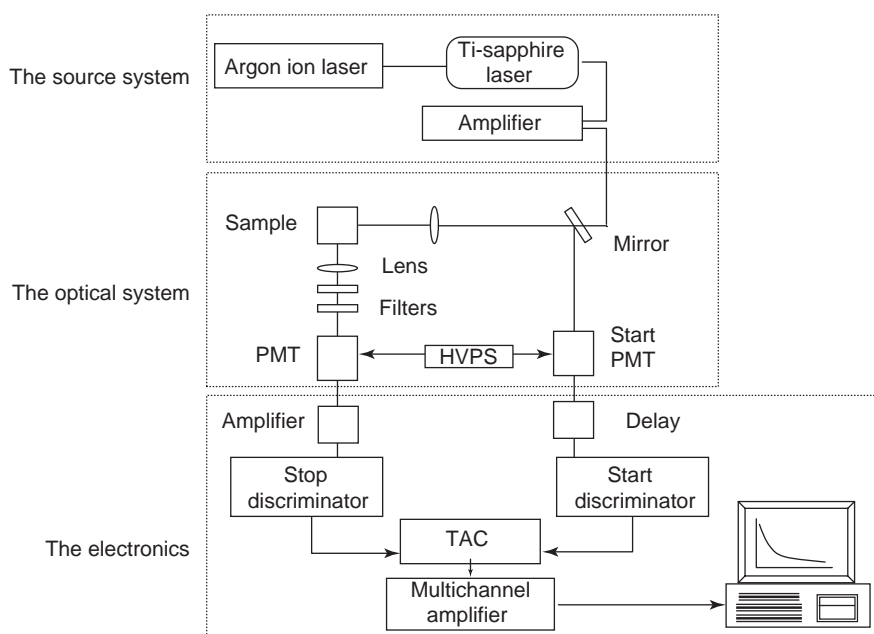

There are basically three choices for pulsed excitation in TCSPC measurements: flashlamps, synchrotron sources, and lasers. Flashlamps and lasers are the most commonly used (see Table 1).

At present, almost all the flashlamps used are gated and their spectral output depends on the gas within them. On the other hand, the pulse width typically depends on both the type of gas and the pressure (Table 1). The main drawback of using a flashlamp for TCSPC is the low repetition rate. The fastest flashlamps have repetition rates up to 100 kHz with 20 kHz being more common.

Lasers are now fast replacing flashlamps. The formation of a pulse for TCSPC by a laser is carried out by a process known as mode-locking, which produces pulses of picosecond duration or less. For a mode-locked laser, a periodic loss is introduced into the laser cavity by some modulator that acts as a shutter, opening once every round trip for the light in the resonator. Among mode-locked lasers, Ti:sapphire lasers pumped by an Argon ion laser is an ultrafast

**Figure 4** TCSPC measurement principle. The random nature of the events recorded yields a luminescence decay histogram. The memory cells are memory addresses to record a photon at a specified time interval.

**Figure 5** Basic TCSPC setup.

**Table 1** Light sources suitable for fluorescence lifetime measurements

Light source	Characteristics
Flashlamps	Hydrogen, deuterium: UV wide range, low intensity Nitrogen: high intensity Ar/H <sub>2</sub> mixtures: nanosecond pulse widths, output up to 750 nm Xenon: for long lifetime samples, UV–IR, intense Nanosecond pulsed xenon commercially available
Picosecond dye lasers	Nd:YAG: fundamental output at 1064 nm, 355 nm (third harmonic), 266 nm (fourth harmonic) Mode-locked argon-ion: output at 514 nm
Femtosecond lasers	Nitrogen/dye: compact and reliable, output at 337 nm, pulse widths between 300 ps and 10 ns Ti:sapphire: solid-state device, long operational life, long-wavelength output 720–920 nm
Solid-state lasers	Simpler, low cost, 600–700 nm (limited range)
Ultrabright LEDs	Nanosecond pulsed, 1–200 MHz, very stable in operation, UV (370–390 nm), blue (470 nm), green (530 nm)

laser system that uses a Ti:sapphire crystal as the gain medium for the near-infrared (NIR) and is tunable from 720 to 990 nm. The Ti:sapphire laser is a solid-state device, with a repetition rate of 76 MHz with 100–150 fs pulses and an extremely long operational life.

Semiconductor diode lasers offer the advantages of low cost, relatively high powers, stable output, and long lifetimes (>40 000 h). These devices, which use a semiconductor material (e.g., GaAlAs) as the gain medium for light production, have also been shown to be adequate excitation sources for TCSPC measurements. A drawback of diode lasers is that the beam-shape is elliptical due to the longitudinal separation between the diode laser's emission points

parallel and perpendicular to the p–n junction. The wavelengths are usually limited to 600–700 nm (some can be frequency-doubled to 410 nm), typical repetition rates up to 80 MHz and pulses of 100 ps.

### Detector Devices

The detector is perhaps the most critical component of the instrumentation. Ultimately, it is its characteristics that dictate the overall timing response of the TCSPC instrument. The main requirements for an ideal SPC detector are:

1. Fast response time, typically <1.5 ns rise time;
2. High gain, typically in excess of  $10^6$ ;

3. Low noise, dominated by dark count and ideally  $<100$  cps;
4. Negligible temporal response dependence on wavelength, ideally  $<0.5$  ps nm $^{-1}$ ;
5. Low detector-generated artifacts;
6. Low transit time jitter across the device's detecting area, ideally  $<20$  ps mm $^{-1}$ ; and
7. Sensitive area compatible with other optical components.

Some of these requirements conflict with each other, such as in the loss of noise performance as the gain is increased. As result, the sensitivity of the TCSPC method is mainly limited by the dark count of the detector. Not all the detectors fulfill the above requirements. Photomultiplier tubes (PMTs) are the most popular type of detector employed in fluorescence lifetime determination by TCSPC. There are two principal types of PMTs used in SPC: the side-on PMT and the linear focused PMT. They operate on the principle of light interacting with either an opaque or semitransparent photocathode liberating photoelectrons which are then multiplied by a dynode structure to provide an electrical output. Each of the PMT geometries has its own advantages and drawbacks, the linear focused type being the more widely used one. In general terms, PMTs exhibit gains  $\sim 10^7$ , fast rise time followed by a rapid and smooth return to the baseline, and low dark counting rate (which is enhanced by cooling).

Defining the sensitivity  $S$  as the intensity at which the signal equals the noise of the dark signal, the following equation applies:

$$S = \frac{(Dkc \times N/T)^{1/2}}{q} \quad [10]$$

where  $Dkc$  is the dark count rate,  $N$  the number of time channels,  $q$  the quantum efficiency of the detector, and  $T$  the overall measurement time. Typical values for a PMT with multialkali cathode without cooling, are  $Dkc = 300$  s $^{-1}$ ,  $N = 260$ ,  $q = 0.1$ , and  $T = 100$  s. This yields a sensitivity of  $S = 280$  photons s $^{-1}$ , a value which is  $10^{15}$  smaller than the intensity of a typical laser ( $10^{18}$  photons s $^{-1}$ ). Then, when a sample is excited by a laser and the emitted light is measured, the emission is still detectable for a conversion efficiency of  $10^{-15}$ .

There are also two detector devices that are gaining popularity for fluorescence lifetime studies due to their fast time response: the microchannel plate photodetectors and streak cameras. Microchannel plate photodetectors, similar to PMTs, are based on the use of multiplication of photoelectrons. Instead of using discrete dynodes, continuous semiconductor-coated glass multiplier tubes of  $\sim 10$   $\mu$ m diameter

are employed. An electric field is applied across the faces of the microchannel plate so that electrons entering the multiplier tubes are accelerated and, on striking the walls, produce secondary electrons. These are then accelerated and cause more electrons to become liberated thus producing electron amplification. These electrons are collected by the anode to deliver an output pulse as in a conventional PMT. Microchannel plate detectors offer extremely fast response at high quantum efficiency throughout UV and visible range. They are best used with laser sources which have a more comparable time profile while conventional PMTs can be used effectively with flashlamp excitation sources.

The photoelectronic streak camera is capable of measuring time dependence of electromagnetic radiation from X-ray to NIR at  $10^{-7}$ – $10^{-13}$  ps resolution. Basically, its operation is based on the conversion of the emitted photon into a photoelectron. The photoelectron beam is then spatially dispersed on a phosphor by a synchronized deflection voltage applied across two plates. In contrast to other detectors, streak cameras provide the additional features of data timing and acquisition. However, their main limitation is the relatively low dynamic range and the high cost. Streak cameras can provide simultaneous measurements of both wavelength and time-resolved decays. Such data are particularly valuable in those situations where very short time resolution is required or in the study of samples that contain fluorophores emitting at different wavelengths.

On examining **Figure 5**, it is observed that the fluorescence channel looks very much like the theoretical system discussed above (**Figure 3**), while the excitation channel is significantly different. Light from the pulsed source is detected by the start photomultiplier, which eventually generate the start pulse. The start signal is then delayed – or slowed down – to prevent it from starting the TAC until some point in time later than it would if the delay device were not present. This delay is necessary because the total light travel time is significantly shorter in the excitation channel than it is in the fluorescence channel. In the absence of the delay device, there is a void space at the low edge of the fluorescence decay profile and a loss of data at the high end. Adding the delay device and adjusting it to eliminate the void space, the lost data at the high end are now recovered (see **Figure 6**). After being delayed, the excitation pulse is sensed by the start discriminator. By setting its high threshold level above the noise level of the detector, the valid output signal will start the TAC. In the fluorescence channel, the same components are used, except for the delay device, and

**Figure 6** Effect of the delay module: (A) no delay module, (B) correctly adjusted start delay.

comments concerning their functions apply in this case as well.

Discriminators are used to aid in removing random noise pulses resulting from background photons, to ensure that the timing definition of the start and stop pulses is largely independent of the signal pulse height and to improve the signal-to-noise ratio. There are two types of discriminators: leading edge (LE) and constant fraction (CF) discriminators. The CF is particularly suited to SPC studies compared to LE as with the LE photodetector pulses of different heights will not cross the discriminator level at the same time, introducing errors into the measurement.

As described above, the TAC functions to determine the time interval between the excitation pulse and the subsequent fluorescence photon arriving at the detector. The MCA consists of an ADC, a memory consisting of channels for storing data, and data input and output facilities. A standard instrument incorporates lower and upper discriminator levels and two modes of data collection: pulse height analysis mode for displaying fluorescence decay profiles ( $\geq 1000$  channels) and multichannel scaling mode to bin the data into given time increments. Data are usually displayed on an oscilloscope or on a computer terminal.

An important aspect associated with lifetime determinations is related with the calculation algorithms or data processing to extract the lifetime value from the resulting decay. There are two algorithms

that are commonly used. The rapid determination method estimates the fluorescence lifetime by integrating the number of counts within the decay profile over a specified time interval from:

$$\tau_f = -\frac{\Delta t}{\ln(D_1/D_0)} \quad [11]$$

where  $\Delta t$  is the time interval over which the counts are integrated,  $D_0$  represents the integrated counts in the early time interval, and  $D_1$  is the integrated number of counts in the later time interval of the decay spectrum. This method can extract only a single lifetime value, which in cases of multiexponential profiles represents an average value of the different components comprising the decay.

Nonlinear least squares method allows to compare the measured data  $N(t_k)$  with values predicted  $N_c(t_k)$  from a model and the parameters of the model to be varied to yield the minimum deviation from the data through minimization of the goodness-of-fit parameter  $\chi^2$ , calculated from

$$\begin{aligned} \chi^2 &= \sum_{k=1}^n 1/\sigma_k^2 [N(t_k) - N_c(t_k)]^2 \\ &= \sum_{k=1}^n [N(t_k) - N_c(t_k)]^2 / N(t_k) \end{aligned} \quad [12]$$

where the sum extends over the number of channels ( $n$ ) or data points used in the analysis and  $\sigma_k$  is the standard deviation associated with each data point. Nonlinear least squares method can analyze multiexponential decays and has the capability to remove the contribution of the instrument response function through deconvolution.

## Phase-Resolved Measurements

Phase-resolved, phase-modulation, or phase-sensitive lifetime measurements are based on the use of a continuous, sinusoidally modulated excitation source and phase-sensitive detection (Figure 7). The experimentally measured parameters are the modulation ( $m$ ) and the frequency-dependent phase shift ( $\Psi$ ). The modulation of the excitation is given by  $b/a$ , where  $a$  is the average intensity and  $b$  is the modulated amplitude of the incident light. For emission, the modulation is similarly defined, except using the intensities of the emission,  $B/A$ , relative to the modulation of the excitation,  $m = (B/A)/(b/a)$ . The phase delay or phase angle ( $\Psi$ ) is usually measured from the zero-crossing time of the modulated components. For an exponential decay, the fluorescence lifetime  $\tau_f$  can be calculated from the phase shift or

demodulation factor as follows:

$$\tau_f = \tan \Psi / \omega \quad [13]$$

$$\tau_f = (m^{-2} - 1)^{1/2} / \omega \quad [14]$$

where  $\omega$  is the angular modulation frequency ( $\omega = 2\pi f$ ,  $f$  = linear modulation frequency in hertz).

**Figure 7** Phase-modulation technique. The ratios  $B/A$  and  $b/a$  represent the modulation of the emission and of the excitation, respectively. (Reproduced with permission from Lakowicz TR (1999) *Principles of Fluorescence Spectroscopy*, 2nd edn., ch. 4, p. 96. New York: Kluwer Academic; © Kluwer Academic.)

Both  $\Psi$  and  $m$  are measured relative to the signal from a scattering solution or a reference fluorophore of known lifetime (see Figure 8). In the former case,  $m$  is the ratio of the modulation depth of the AC waveform of the fluorophore to that for a scattering solution. The reference signal  $I_r(t)$  that tracks the time-dependent excitation radiance is obtained by directing part of the excitation beam to the scattering solution and monitoring the scattering signal. In this case

$$I_r(t) = (I_r)_{DC}(1 + d_m \sin \omega t) \quad [15]$$

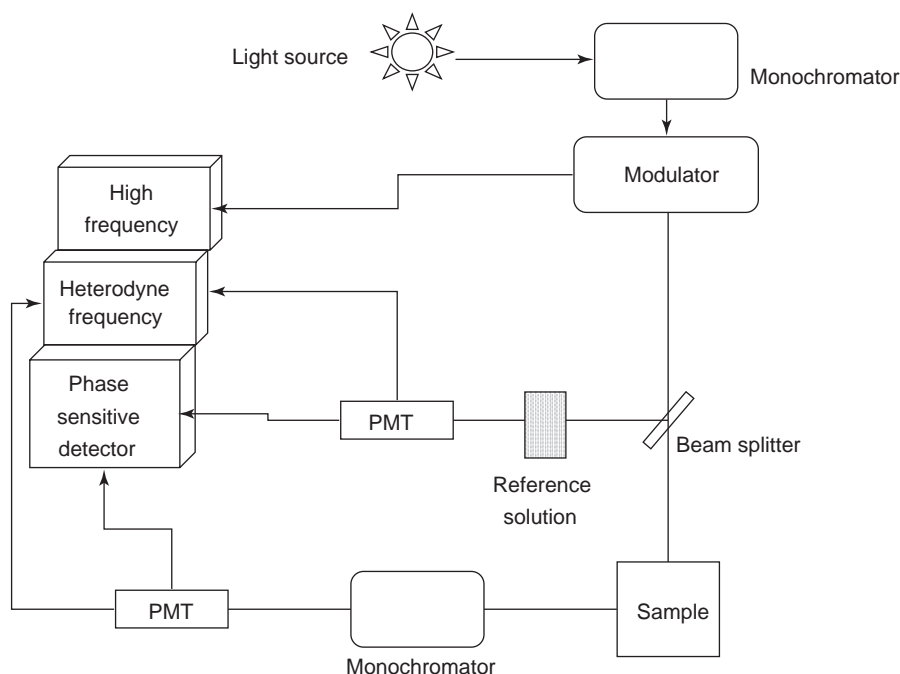

where  $(I_r)_{DC}$  is the magnitude of the DC component,  $d_m$  is the modulation depth of the AC component (i.e., the ratio of the AC to DC amplitude of the excitation radiance). If the modulation period is on the order or smaller than the fluorescence lifetime, the resulting fluorescence signal is demodulated and phase shifted as shown in Figure 7.

The time-dependent fluorescence signal  $I_f(t)$  is described by

$$I_f(t) = (I_f)_{DC}[1 + d_m m \sin(\omega t - \Psi)] \quad [16]$$

where  $(I_f)_{DC}$  is the DC component of the fluorescence signal.

The values of  $\Psi$  and  $m$  can also be compared by nonlinear regression to the values predicted from an assumed decay law. So, for any time-domain decay law (eqn [7]), the frequency-domain data are related

**Figure 8** Block diagram of a phase fluorimeter with phase-sensitive detection.

by the sine and cosine Fourier transforms

$$N_{\omega} = \frac{\int_{-\infty}^0 I(t) \sin \omega t \, dt}{\int_{-\infty}^0 I(t) \, dt} \quad [17]$$

$$D_{\omega} = \frac{\int_{-\infty}^0 I(t) \cos \omega t \, dt}{\int_{-\infty}^0 I(t) \, dt} \quad [18]$$

These are related to the experimentally measured parameters through the expressions:

$$\tan[\Psi(\omega)] = [N(\omega)/D(\omega)] \quad [19]$$

$$[m(\omega)] = [N^2(\omega) + D^2(\omega)]^{1/2} \quad [20]$$

The decay terms ( $\alpha_i$  and  $\tau_i$ ) are recovered by minimization of the  $\chi^2$  function

$$\begin{aligned} \chi^2 = 1/\nu \sum_{\omega} [\Psi_{\omega} - \Psi_{c\omega}/\delta\Psi]^2 \\ + 1/\nu \sum_{\omega} [m_{\omega} - m_{c\omega}/\delta m]^2 \end{aligned} \quad [21]$$

where  $\nu$  is the number of degrees of freedom, and  $\delta\Psi$  and  $\delta m$  are the uncertainties in the measured phase and modulation, respectively. The subscript c denotes the frequency-dependent phase and modulation calculated on the basis of  $\alpha_i$  and  $\tau_i$ .

The excitation beam (He–Cd laser, laser diode, LED) is usually modulated with an electro-optic modulator and modulation frequencies vary typically from 10 to 200 MHz. The modulated fluorescence signal is extracted by synchronous detection with a lock-in amplifier. The detector of choice in frequency-domain fluorescence is a PMT. In order to process the signals, the PMT bias voltage and hence the PMT gain is modulated at frequency  $\omega + \Delta\omega$  to produce a heterodyne signal at  $\Delta\omega$ . In this way, high-frequency signals are shifted to low-frequency signals, which are easier to process. Resolution as good as 1–100 ps is possible.

## Analytical Applications

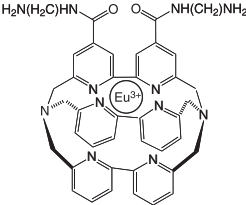

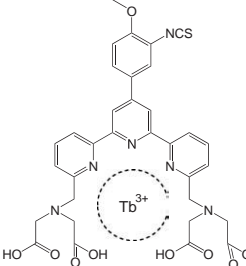

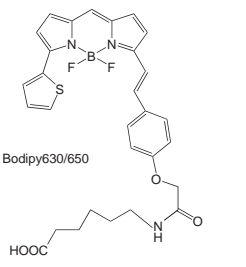

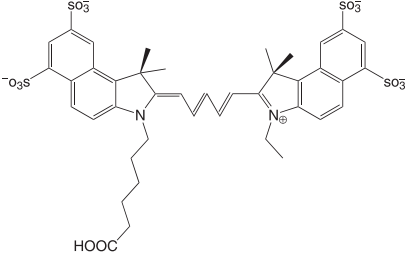

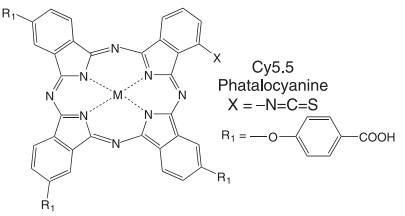

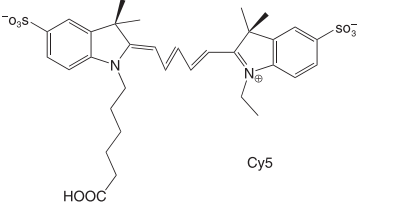

Fluorescence is unique among spectroscopic techniques due to its inherently multidimensional nature, the emission process containing a wealth of orthogonal information that is related to the fluorophore and its surroundings. Time- and frequency-domain fluorescence methods are instrumentally sophisticated, but they improve both the sensitivity and selectivity of fluorimetry. Any dye that is used for steady-state fluorescence detection can be used for time-resolved detection as well. Most of these fluorophores display lifetimes from 1 to 10 ns, which requires fast electronics for time-domain lifetime measurements or modulation frequencies from 10

to 100 MHz for frequency-domain measurements. However, fluorophores with considerably longer lifetimes have been used in assays based on time-resolved fluorescence techniques. For instance, fluorescent lanthanoid chelates have some unique features such as long lifetime sometimes exceeding 1 ms, large Stokes shifts ( $>250$  nm) and very sharp peak profiles with full-width at half-maximum of  $\sim 10$  nm. These fluorescent chelates can be bound to proteins, nucleic acids, and other molecules. Also, some NIR fluorescent tricarbo-cyanine dyes can be used in time-resolved identification of multiple dyes in capillary electrophoresis applications. These dyes show absorption/emission maxima  $\sim 765$ – $794$  nm with lifetimes ranging from 947 to 847 ps. The attractive feature associated with fluorescence in the NIR is the low backgrounds observed during signal collection and the simple instrumentation required for ultrasensitive detection. On the other hand, by incorporation of a heavy atom group into the dye structure the fluorescence lifetime is altered. This is due to the intramolecular heavy-atom effect and internal conversion that result in an increase in  $\tau_f$  with the increasing molecular weight of the substituent group. In **Table 2**, the structure of some chelators and the fluorescent properties of some long-lived fluorophores are shown.

Time- and frequency-domain fluorescence methods have been used in different fields for several purposes, such as distinguishing sample constituents whose fluorescence spectra overlap one another, to distinguish the fluorescence of an analyte from background scattering or luminescence of other sample constituents, in combination with fluorescence resonance energy transfer (FRET) assays to combine the benefits of FRET and time-resolved fluorescence. A listing of some selected applications is given in **Table 3**.

The future of fluorescence spectrometry is indeed promising. The study of liquid/liquid, liquid/solid, and solid/liquid interfaces is of critical importance to protein adsorption, bioadhesion, biosensors, and separation sciences. The analytical potential of time- and frequency-domain techniques in this area is waiting to be explored. The advent of high power pulsed lasers, fast electronics, electro-optics and/or frequency upconversion techniques may allow to study femtosecond processes, such as solvent relaxation and in high-speed problems, for instance, in genome sequencing and capillary separations there is a push to achieve single molecule detection. Today it is possible to obtain time- and frequency-domain decay traces on the fly in a time frame substantially less than 1 s. At present, many fluorescence experiments in these challenging fields may become almost prohibitive. The key factor is to bring down the cost

**Table 2** Long-lived fluorophores

## Introduction

Fluorimetric analytical methods generally have detection limits from one to four orders of magnitude

lower than the corresponding methods based on absorption. A method to further improve detection limits along with increasing selectivity is by fluorescence derivatization procedures through which weakly fluorescent or nonfluorescent species are converted into highly luminescent products. Also, derivatization procedures are important for the determination of substances that tend to decompose during the analysis or for those substances that do

not exhibit the desired properties for a selected transduction scheme. Thus, fluorescence derivatization includes all those procedures that involve reacting the species of interest to yield a fluorescent product. An ideal derivatizing reaction should fulfill some specific analytical criteria that depend on the intended application. In general, desirable properties for fluorescence derivatizing reactions include the following:

1. Fast under mild conditions, quantitative, specific for the compound of interest and simple to perform.
2. The resulting derivative should be stable, not undergo rapid decomposition, and no occurrence of side reactions. These characteristics are especially important in chromatographic precolumn derivatization reactions because side-products may cause interfering peaks in the chromatogram.
3. Measurable differences in spectroscopic properties between the label and its reaction product.
4. The resultant derivative should exhibit reasonably good Stokes' shift and emit fluorescence at long excitation and emission wavelengths in order to avoid background fluorescence from substances present in the sample.
5. The fluorescence efficiency of the derivative should be high for maximum sensitivity.
6. In the analysis of biological samples, it is desirable that the derivatization reagent is water soluble or miscible in aqueous solvents.
7. When used in combination with chromatographic systems, the separation of the resulting derivative and the label must be relatively easy to perform.

Various reactions may be used to convert nonfluorescent species into fluorescent ones. The main advantages as well as the drawbacks of each method will be overviewed. The scope of this article covers those reaction systems not considered elsewhere in this encyclopedia.

## Survey of Derivatization Reactions

Fluorescent derivatization reactions may be classified into seven groups according to the type of reaction involved.

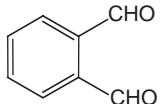

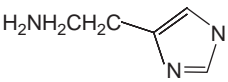

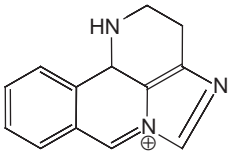

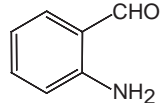

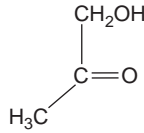

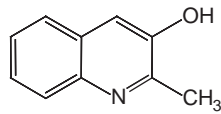

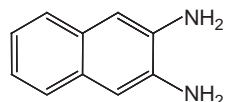

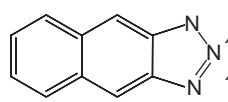

### Reactions That Lead to the Formation of an Extended Aromatic $\pi$ -Electron System

Relatively few aliphatic or alicyclic compounds show analytically useful fluorescence in the ultraviolet (UV) or visible region. On the contrary, efficient fluorescence occurs in molecules having extended

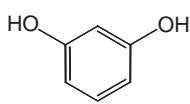

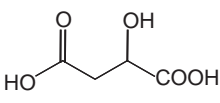

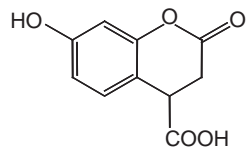

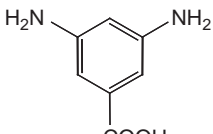

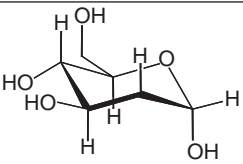

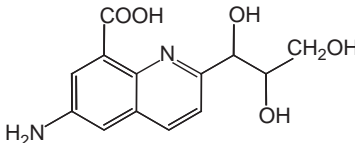

$\pi$ -electron systems. Generally, the efficiency of the fluorescence increases with the rigidity of the molecular structure as well as with the planarity of the structure, both of which are considered to be requirements for effective  $\pi$ -electron delocalization. A practical consequence of these facts for fluorescence derivatization is that most important fluorescence derivatization reactions involve the formation of compounds with at least two condensed aromatic rings. Representative examples are given in Figures 1–3; they are classified according to the manner in which the aromatic  $\pi$ -electron system is formed. Thus, in Figure 1, the reaction of aromatic hydrocarbon compounds with two adjacent substituents, both of which combine with the analyte, produce a new ring. Another method to extend the  $\pi$ -electron system is by coupling the analyte to a substituent and to an unsubstituted position on an aromatic ring (Figure 2). Substituted aromatic compounds may be the analyte, giving rise to reactions based on the same principles (Figure 3). In general, these kinds of reactions are performed in hard conditions (strong acid, elevated temperatures, long reaction times) and, as a result, the structure of the fluorescent product is, in many cases, unknown. Most of the reactions result in the formation of heterocyclic compounds, for which the lowest energy electronic transition is  $n, \pi^*$ . Accordingly, we can expect such compounds to show low fluorescence efficiency. However, the presence of electron-donating groups and the extended  $\pi$ -systems minimizes the influence of the lone pair on the heteroatom, and fluorescence from the lowest singlet state  $\pi, \pi^*$ , rather than  $n, \pi^*$ , may be observed. The formation of the extended  $\pi$ -system is accompanied by a red-shift in the fluorescence band with respect to that of the reagents, which eliminates the need for the removal of residual fluorescent reagents. This fact is directly translatable into lower background signals. Many of these reactions are not specific for an analyte, but the selectivity for a group of compounds is rather good.

### Oxidation/Reduction

Fluorescence derivatization reactions that involve oxidation and/or reduction steps have been employed for determining compounds of biological and environmental interest. Common oxidizing agents include hydrogen peroxide, potassium permanganate, cyanogen bromide, and strong mineral acids, depending on the specific application. Typical examples include the fluorimetric determination of cholesterol, based on the well-known Liebermann–Bouchard reaction, in which cholesterol is reacted with chloroform and acetic anhydride in concentrated sulfuric acid. The method is not specific and

Reagent	Analytes	Reaction conditions	Fluorescent product
 O-Phthalaldehyde	 Histamine, indoles, peptides, proteins	Basic	 $\lambda_{\text{exc}} = 360 \text{ nm}$ $\lambda_{\text{em}} = 490 \text{ nm}$
 O-Amino-benzaldehyde	 Carbohydrates	KOH/boiled	 Blue emission

Reagent	Analytes	Reaction conditions	Fluorescent product
 Resorcinol	 Keto-hexoses, ketoacids, dicarboxylic acid	$\text{H}_2\text{SO}_4$ 50% 20 min 60°C	 $\lambda_{\text{exc}} = 430 \text{ nm}$ $\lambda_{\text{em}} = 480 \text{ nm}$
 3, 5-Diamdiamo-benzoic acid	 2-Deoxy-D-glucose Acetaldehyde DNA	$\text{H}_3\text{PO}_4$ 15 min 100°C	 $\lambda_{\text{exc}} = 410 \text{ nm}$ $\lambda_{\text{em}} = 500 \text{ nm}$

**Figure 2** Extended aromatic  $\pi$ -electron systems by coupling to an unsubstituted position of an aromatic ring.

other steroids also give a similar reaction. This procedure has been applied for the determination of cholesterol in serum samples. Vitamin B<sub>1</sub> (thiamine) is also easily decomposed by oxidizing agents

(ferricyanide, cyanogen bromide, mercuric oxide) and by UV light. The procedure involves the oxidation of thiamine to form the fluorescent thiochrome fluorophore (Figure 4).

Reagent	Analytes	Reaction conditions	Fluorescent product
 Ethyl acetoacetate	 Phenols	H <sub>2</sub> SO <sub>4</sub>	 $\lambda_{\text{exc}} = 366 \text{ nm}$ $\lambda_{\text{em}} = 460 \text{ nm}$
 Chloro-acetaldehyde	 Adenine compounds	pH 6 30 min 100°C	 $\lambda_{\text{exc}} = 310 \text{ nm}$ $\lambda_{\text{em}} = 410 \text{ nm}$

**Figure 3** Derivatization reactions based on extended aromatic  $\pi$ -electron systems for substituted aromatic analytes.

**Figure 4** Derivatization of vitamin B<sub>1</sub> by reaction with oxidizing agents.

The direct fluorimetric determination of catecholamines based on their native fluorescence (excitation at 275 nm, emission at 318 nm) lacks sensitivity and is susceptible to chemical interference from biological sample matrices (serum, urine). Therefore, in order to improve sensitivity and selectivity, catecholamines can be derivatized by oxidation with ferricyanide or iodine followed by addition of an alkali containing an antioxidant. The alkali causes the rearrangement of the oxidized compounds to yield 3,5,6-trihydroxyindole, an intensely fluorescent product (**Figure 5**). This is one of the most sensitive and widely used methods for derivatizing catecholamines and has been used as postcolumn detection mode after chromatographic separation of the amines. Detection limits in the picomole range have been reported. In some instances, the oxidation is followed by a condensation with an adequate reagent

in order to extend the  $\pi$ -electron system. For example, after oxidation of catecholamines with ferricyanide, condensation with ethylenediamine results in a fluorescent product that shows maximal excitation at 420 nm and maximal fluorescence at 490 and 520 nm.

Anion fluorimetric assays may also be developed through redox reactions. For instance, cyanide ions react with *p*-benzoquinone to form a highly fluorescent derivative, with the cyanide ion acting as a reducing agent. Other anions such as thiocyanate and sulfide do not interfere and a sensitivity range of 0.2–50  $\mu\text{g ml}^{-1}$  has been reported. In a same way, nitrite converts quantitatively a nonfluorescent reagent, 7-amine-methyl-amino-4-nitrobenzoxadiazole, into a highly fluorescent product. Nanomolar concentrations of nitrite can be determined in water samples (see **Figure 6**).

**Figure 5** Fluorescence derivatization of catecholamines by oxidation.

**Figure 6** Anion fluorimetric derivatization through redox reactions.

It is also feasible to use enzymatic assays as an alternative to chemical oxidation/reduction. Many of these enzymatic assays are based on the fluorescence of the reduced form or the oxidized form of the

enzyme cofactor. For example, NADH and NADPH are highly fluorescent, while the oxidized form of NADH and  $\text{NAD}^+$  is nonfluorescent. The excitation and emission wavelengths commonly used are 340 and 450 nm, respectively. The cofactor pyridoxal phosphate is also fluorescent and its absorption and emission spectra are dependent on its chemical structure in the protein. Ribo flavin, flavin mononucleotide, and flavin adenine dinucleotide absorb light in the visible range ( $\sim 450 \text{ nm}$ ) and emit around 525 nm and, in contrast to NADH, the oxidized forms of flavins are fluorescent. The derivatization approach is based either upon the forward reaction when the cofactors (e.g., NADH or NADPH) are the products or upon the reverse reaction in which they are oxidized (e.g., to NAD and NADP) or reduced. Two basic approaches may be distinguished: timed and kinetic. In the timed method, fluorescence is measured after a fixed time; in the kinetic method, the rate of fluorescence change is measured. Depending on the reaction conditions, the kinetic approach can be used for the determination of substrate, enzyme, activator, or inhibitor concentrations, while the timed method is useful for the determination of substrate only, in which a large excess of enzyme over the substrate (analyte) concentration is used to ensure a relatively complete reaction. Many enzymatic assays involve NADH as a reactant or product and a number of analyses based on NADH measurements are feasible. These reactions are employed in many areas. For example, a frequent scheme for fluorimetric determination of ethanol in blood plasma, various foods, and beverages is the reaction:

(in presence of alcohol dehydrogenase as an enzyme). The potential sensitivity of these reactions can be enhanced by a procedure known as coupled assays. A simple coupled assay for the determination of hexokinase activity by coupling the formation of glucose-6-phosphate to the reduction of  $\text{NADP}^+$  in presence of glucose-6-phosphate dehydrogenase is:

The fluorimetric indication of NADH has also been used in optical biosensors for lactate, pyruvate, and ethanol, where the respective dehydrogenase was immobilized at the tip of an optical NADH sensor.

### Hydrolysis Reactions

Hydrolysis is one of the most simple treatment methods to convert nonfluorescent compounds to fluorescent ones. It is usually accomplished in a strongly alkaline aqueous medium and, in some cases, at a high temperature, resulting in the formation of fluorescent anions. Thus, acetylsalicylic acid (aspirin) has weak native fluorescence, but its base-hydrolysis conjugate, the salicylate ion, strongly fluoresces at  $\sim 400$  nm after it has been excited at about 310 nm. This property has been used to determine aspirin and salicylates directly in serum, urine, and plasma samples. In the same way, hydrolysis has been successfully applied to the determination of carbamate pesticides and organophosphorus insecticides, with detection limits in the low nanogram range. The sensitivity could be improved after heat treatment of the hydrolysis products even for many pesticides.

### Photoconversions

After exposition to UV radiation some compounds can be converted to highly fluorescent species.

Typical examples of this approach are the fluorimetric determination of the anabolic agent diethylstilbestrol in urine and the fluorimetric determination of different pesticides (see Figure 7). After a simple extraction step, the analyte may be separated from interfering substances using high-performance liquid chromatography (HPLC) and the derivative detected fluorimetrically. In spite of its simplicity, photochemical derivatization has been much less applied than chemical derivatization. The main advantages include: (1) there is no need to use chemicals, and therefore dilution is avoided; (2) fast reaction rates since most photochemical reactions take place via free radicals; (3) easy to perform, requiring inexpensive equipment; (4) the use of room temperature (compared to thermally initiated derivatization) makes the technique suitable for various experimental conditions (e.g., flow-injection analysis (FIA), dynamic systems, HPLC, thin-layer chromatography (TLC), and stationary liquid solutions); and (5) the structure of the fluorescent compound need not necessarily be known provided that reproducible fluorescence signals are obtained. Photoconversion has also some drawbacks, relative to conventional derivatization methods, such as the possible formation of nonfluorescent photoproducts, secondary thermal reactions, and/or photodegradations leading to nonstable and difficult to identify photoproducts, particularly those responsible for fluorescence emission.

**Figure 7** Fluorimetric derivatization by photoconversion.

FBM, fluorimetric batch method; FIA, flow-injection analysis; SDS, sodium dodecyl sulfate; 2,4-D, 2,4-dichlorophenoxyacetic acid.

Some parameters affect the conversion of nonfluorescent compounds into fluorescent ones, e.g., UV irradiation time and the nature of the solvent used (see Table 1). For example, pesticides such as fenvalerate, diflubenzuron, and deltamethrin are efficiently converted into fluorescent products (high signal with short irradiation time) in protic solvents, while for fenitrothion and chlorpyrifos polar aprotic solvents are the choice. Comparing the analytical performances of the photoconversion method with other derivatization approaches, it can be considered a rapid, sensitive, and precise method for quantifying several classes of pesticides in stationary media and as postcolumn detection mode in HPLC and in FIA.

### Complexation

Complexation involves the combination of a metal ion with a weakly fluorescent or a nonfluorescent compound containing chelate-forming, electron-donating functional groups to form highly fluorescent metal chelates. Thus, aromatic molecules that have  $n-\pi^*$  lowest excited singlets when they are not complexed, have  $\pi-\pi^*$  lowest excited singlets when they complex with a metal ion. Thus, a nonfluorescent structure becomes fluorescent. This effect can be used for the analysis of either the metal ion or the organic substance, although metal ion determinations enjoy the widest application.

There are some interesting features related with metal complexation. If the metal is paramagnetic (e.g.,  $\text{Fe}^{3+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Cu}^{2+}$ ), an increase in intersystem crossing from the  $S_1$  state to the  $T_1$  state of the aromatic ligand takes place, which causes a decrease in fluorescence. Another phenomenon that operates in metal complexation to prevent fluorescence is the heavy atom effect. Heavy diamagnetic atoms such as  $\text{Hg}^{2+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Ag}^+$ , or  $\text{Tl}^{3+}$  increase

spin-orbit coupling, which increases the rate of intersystem crossing. On the other hand, some group VIII  $d^6$  transition metal ions (e.g., ruthenium(II), rhodium(III), iridium(III), and osmium(II)) form fluorescent complexes with strong-field ligands such as 1,10-phenanthroline, 2,2-bipyridine, and 2,2,2-terpyridine. These chelates exhibit low-energy charge-transfer  $d \rightarrow \pi^*$  absorption and  $\pi^* \rightarrow d$  emission bands. Ruthenium(II) polypyridine complexes have been extensively used for luminescence oxygen-sensing applications due to the fact that they are very stable, exhibit high quantum yields, and are readily quenched by oxygen.

The basic requirement of the organic chelating reagent for fluorescence derivatization is its capacity to covalently bound with the metal ion through at least two functional groups to form a rigid structure. Ions most frequently measured by fluorescence are nontransition-metal ions, in particular those in group IIIA – aluminum(III), gallium(III), indium(III), and thallium(III) – which form metal chelates with a number of organic ligands (see Figure 8). The ligands are usually weakly fluorescent when uncomplexed and the major means of exciting the chelates is by using the  $\pi-\pi^*$  absorption bands of the chelated ligand. It is noteworthy that sensitivity of traditional analytical fluorimetric techniques for metal ions is enhanced in the presence of micelles. This effect arises from a number of interactions, among which those of the metal complex with the special microenvironment provided by micelles diminish vibrational quenching, enhance solubility, and alter the intrinsic photochemical properties of the chelate.

Under optimal reaction conditions, some organic compounds are highly specific for certain metal ions, thus resulting in highly selective fluorimetric methods for those ions, and the preconceived idea that fluorescence methods for metals do not offer significant

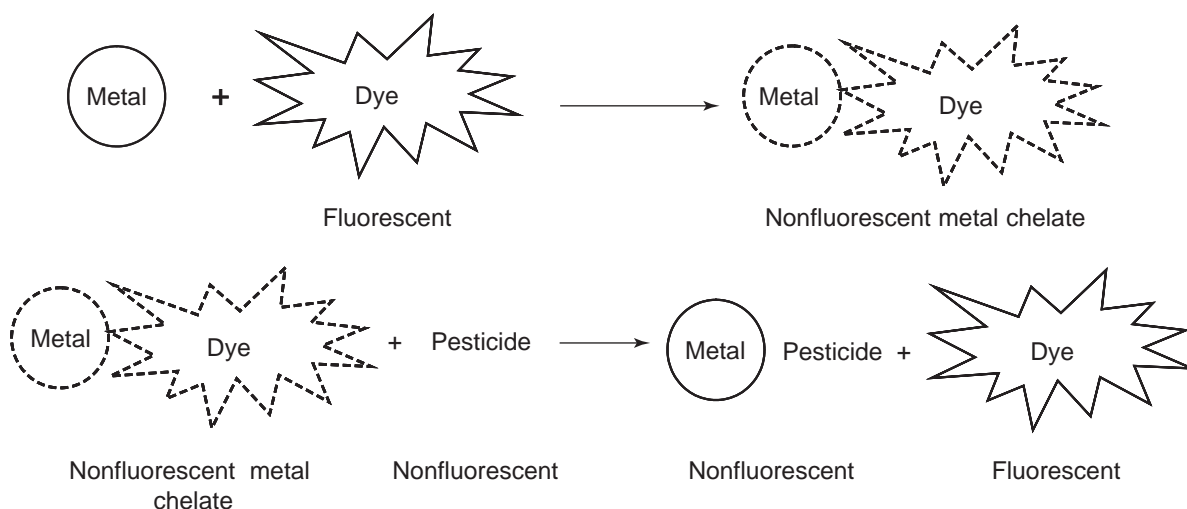

**Figure 8** Fluorescent metal complex formation.

advantages over other competing techniques, such as atomic methods (e.g., atomic absorption or inductively coupled plasma) is misleading in many situations. For example, fluorescence is the best technique for noninvasive measurements in living cells. The advent of ion-sensitive fluorescent dyes has unleashed the power of fluorescence for biomedical and life science research to identify and measure biologically significant nonfluorescent substances. Thus, calcium, magnesium, sodium, and other metal ion concentrations can be fluorimetrically measured inside cells by complexation with fluorescent dyes designed to exhibit a high affinity for a specific ion (e.g., Fura-2 is specific to calcium ions). The introduction of these ion-sensitive dyes in 1985 gave birth to the quantitative ratio fluorescence technique. The dye binds to a negligible amount of ions as compared to the total quantity of the ion species, and so it does not significantly alter the statistical equilibrium of bound and free ions. When the free ion concentration changes, the equilibrium between free indicator and ion-bound dye also changes, resulting in a change in the fluorescence properties of the indicator dye. The key characteristic of these indicators is a wavelength shift that may occur in either the excitation or the emission spectrum. An example of a dual excitation indicator is Fura-2. Its fluorescence excitation maximum

shifts from 372 nm in the absence of calcium to 340 nm when bound to calcium. In both cases, the fluorescence emission intensity is measured at 510 nm. Calcium quantitation can be performed by rationing the fluorescence intensities at the two excitation wavelengths. Since this measurement approach is based on intensities derived from the excitation spectrum, the calcium concentration measurement is independent of dye concentration and optical pathlength, parameters that cannot be controlled within a cell. Also, photodegradation of the dye due to prolonged illumination and variations in the excitation source do not compromise ratio fluorescence measurements.

In addition to direct metal analysis, indirect analysis for ligands that pull away the metal ion from the fluorescent metal chelate, is also possible. In this case, a decrease in fluorescence is observed. For example, fluoride causes the fluorescence of the aluminum–Eriochrome Red B complex to decrease. In a similar way, nonfluorescent metal chelates can be used for the fluorimetric analysis of nonfluorescent analytes via a ligand-exchange reaction, according to the scheme shown in **Figure 9**. In the first step a nonfluorescent complex is formed between a fluorescent chelator and a metal ion. In the next step the addition of the pesticide induces the displacement of the fluorescent ligand and then combines with

**Figure 9** Indirect fluorimetric analysis via ligand-exchange reactions.

the free metal ion. The pesticide concentration is then proportional to the free fluorescent dye. Using palladium as the metal ion and calcein as the fluorophore, detection limits in the nanogram range have been reported for organophosphorus pesticides using TLC. In a similar way, the use of the fluorescent  $\text{Al}^{3+}$ -Morin complex as a postcolumn reagent in HPLC allows the indirect sensitive detection of phosphonic pesticides by monitoring the  $\text{Al}^{3+}$ -Morin fluorescence decrease in the analyte band due to the presence of the phosphoric group.

Alternatively, direct analysis of nonfluorescent organic ligands by adding an excess of metal ion to form fluorescent compounds is also possible. Although this derivatization strategy has attractive analytical potential for the analysis of nonfluorescent aromatic compounds, it has received little attention. A typical example includes the fluorimetric determination of anthracyclines and tetracyclines as metal chelates with  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Eu}^{3+}$  under neutral or alkaline solutions, and with  $\text{Al}^{3+}$  or  $\text{Zr}^{4+}$ , under acidic conditions.

Metal complexation reactions are very convenient for fluorescence derivatization as they are fast and can be driven to completion by adding excess of reagent. These characteristics made them especially suitable for postcolumn derivatization in chromatographic separations, HPLC, and capillary electrophoresis (CE). An example of the use of complexation reaction is a CE postcolumn method developed for the determination of catecholamines and related compounds. The method is based on the ternary complex formed with  $\text{Tb}^{3+}$  ions, ethylenediaminetetraacetic acid and the catecholic

compound. Excitation of such a ternary complex at the absorption wavelength of the catecholic compound (the donor) results in the typical  $\text{Tb}^{3+}$  emission (sensitized luminescence of the acceptor). Detection limits are in the  $10^{-7} \text{ mol l}^{-1}$  range. Also, metal complexation can be used as a sensitive fluorimetric detection approach to metal ion speciation. For example, morin (2',3,4',5,7-pentahydroxyflavone) forms highly fluorescent complexes with mono- and di-organotin compounds in organic nonpolar media, while those with tri-organotin complexes are weakly fluorescent. As the reactions involved are simple and the kinetics very fast, derivatization is usually coupled to HPLC in the postcolumn mode.

### Quenching Reactions

Derivatization methods based on quenching make use of the heavy atom effect, the paramagnetic nature of the analyte, and/or any event that affects one or more of the photophysical and photochemical aspects related to a fluorophore. The quencher is usually a nonfluorescent species and a major obstacle in fluorescence-quenching-based methods is to find a fluorophore that is selectively quenched by the target analyte. Additionally, as a consequence of the quenching process itself, fluorescence quenching is much less sensitive than the direct emission-based approach. The decrease in intensity with increasing quencher concentration and the short fluorescence decay time mean that the magnitude of the Stern-Volmer constant  $K_{SV}$  is  $\sim 100$ . In this situation, dynamic quenching is measurably observed when the quencher concentration exceeds  $\sim 10^{-4} \text{ mol l}^{-1}$ .

Quenching methods have been used to analyze inorganic anions. Thus, halide ions have been analyzed using indicator fluorescence quenching, with iodide being the most efficient quencher and chloride the least effective. In the same way, electrophilic bromination of fluorescein to yield the low fluorescent 1,3,6,8-tetrabromofluorescein has been used for bromine determination, and a displacement reaction using a nonfluorescent  $\text{Hg}^{2+}$  metal chelate has been described for sulfide determination.

Oxygen is known to be a potent quencher of fluorophores due to its paramagnetic nature. There are a host of fluorophores that are efficiently quenched by oxygen among which the above-mentioned complexes of ruthenium and several polycyclic aromatic hydrocarbons are commonly used. This fact has been exploited to measure oxygen dissolved in water, in blood, and in gas phase as the approach allows oxygen measurement over a wide range of concentrations. Besides oxygen, quenching of fluorescence has also been used to determine a number of gases, including sulfur dioxide, ammonia, hydrogen chloride, oxides of nitrogen, as well as various volatiles such as chloroform, water vapors, and halothane. Moreover, several gas sensors and biosensors based on fluorescence quenching have been developed. Sensors based on fluorescence quenching are particularly suitable for dissolved gas measurements due to the high diffusibility of the gases through suitable polymer membranes used to immobilize the fluorophore.

### Extrinsic Fluorescent Tagging

As many biologically important analytes do not exhibit efficient detection properties (UV or visible light absorption, fluorescence, or electrochemical activity), their detection limits are relatively low. For example, drugs with chiral centers exist naturally in racemic mixtures that are optically inactive due to the nearly equal proportion of the enantiomers. The determination of enantiomeric purity is of paramount importance in the pharmaceutical industry as each enantiomer may have different therapeutic characteristics. Currently, a method that offers multiple advantages for chiral separations is by converting enantiomers to diastereomers by precolumn derivatization with a pure fluorescent enantiomer. For instance, propranolol existing in racemic form may be analyzed by precolumn derivatization with (+)-1-(9-fluorenyl)ethyl chloroformate. Well correlated calibration plots were found up to 400 pmol and a reproducibility of <2% for each derivative.

Two types of fluorescence derivatization reactions can be distinguished for biologically important molecules: covalent and noncovalent reactions. In covalent procedures a covalent bond is formed between the analyte and the fluorescent tag. All other types of chemical interactions (e.g., ion-pairing, intercalation, electrostatic interaction) are grouped into noncovalent reactions. Covalent derivatization reactions of interest for biological or medical assays are covered elsewhere in this encyclopedia. Most of these reactions have been used as HPLC and CE precolumn derivatization methods and most of the fluorogenic reagents have been synthesized on the basis of fundamental structures such as coumarin, quinoxaline, benzofurazan, xanthene, etc. Postcolumn fluorescence derivatization is usually carried out when multiple products are obtained or when the resultant fluorescent derivative is not stable enough during the chromatographic process, but the rate of derivatization is rapid. In summary, a wide variety of fluorogenic derivatization reactions are available for applications to organic and inorganic substances in a wide range of disciplines, e.g., chemistry, biochemistry, medicine, pharmaceutical, forensic, and environmental. With increasing availability of suitable fluorogenic reagents and detectors, fluorescence derivatization is also being increasingly applied. Fluorophores currently used as derivatization reagents offer wide variations of chemical and spectrochemical characteristics to the analyst in tuning the chemistry to his/her particular needs for improved detection (direct or indirect methods, steady-state measurements, kinetic methods, etc.) or to meet requirements imposed by available instrumentation (e.g., wavelength of excitation).

### Quantum Dots as Alternative Labels

The last few years have seen a growing interest in the use of quantum dots (QDs) in biological and chemical sensing applications, as well as for electronic devices and quantum dot lasers. QDs are a new type of fluorescent derivatization/labeling reagents. QDs are nanometer size particles ( $10^{-9}$  m) with special optical properties, composed of a semiconductor material, cadmium selenide (CdSe), which has been coated with an additional semiconductor zinc sulfide (ZnS) shell. This core-shell structure is further coated with a polymer shell that allows to be conjugated to biomolecules, while retaining the optical properties of the QD. The interactions of the QDs with target molecules or with their environment depend strictly on the nature (functionalization) of this polymer layer. For example, the QDs can be capped

**Figure 10** Fluorescent quantum dot covalent derivatization.

with an organic layer such as mercaptoacetic acid, trioctyl phosphine/trioctylphosphine oxide mixture, or with a biomolecular (antibody, oligonucleotide, streptavidin) shell. To date, biomolecules can be linked to QDs mainly by covalent attachment, electrostatic attraction, hydrogen bonding interactions, and hydrophobic forces (see **Figure 10**). As an alternative to conventional fluorophores, QDs have several attractive features, including high emission quantum yields, sharp emission spectra, highly resistant to chemical and metabolic degradation, high photostability, tunable color through the whole spectrum, long lifetimes, and shelf life. The color and optical properties of QDs can be tuned to any chosen wavelength by simply preparing them in a different size or composition. QDs can be detected at concentrations comparable to organic dyes by conventional fluorescence methods and individual bioconjugated QDs are observable by confocal microscopy. Novel QD-conjugates are potentially useful in numerous fluorescence tagging applications, for developing homogeneous bioassays, and as multicolor fluorescent labels for ultrasensitive detection and imaging. In conclusion, the future of QD labeling concept

appears promising for developing novel biosensing technologies, for noninvasive molecular imaging, and for medical diagnostics, pharmacogenomics, and drug discovery.

### Introduction

Fluorescence labeling procedures convert nonluminescent or weakly luminescent molecules into highly fluorescent products. With the aid of specific probes, and in combination with appropriate detector systems, chemical and biochemical systems become amenable to fluorescence spectroscopy. The fluorescence labeling technology has opened new horizons in biosciences, especially in biomedical sciences. It is worth mentioning that fluorescence labeling is made use of in fields ranging from genomics to proteomics, and in areas such as DNA sequencing, protein quantification, polymerase chain reaction (PCR) product analysis, or Western, Northern, and Southern blotting.

The first methods used to label molecules and thus make them quantifiable, employable radioactive isotopes.  $^{125}\text{I}$  isotope is still in use today due to its small size and due to its low detection limit of  $\sim 10$  amol ( $1 \text{ amol} = 10^{-18} \text{ mol}$ ). In spite of the advantages of radioactive labeling, there are a number of disadvantages. For example,  $^{125}\text{I}$ -labeled antibodies cannot be stored for longer than a month, and  $^{32}\text{P}$ -labeled nucleotides decay significantly in about a week. On the contrary, fluorescent labeled biomolecules can be stored for 6 months or longer. In fact, fluorescent labeled reagents can be prepared in a large scale, standardized, and used for extended periods, which minimizes reagent variability between assays. Handling of radioactive materials requires adequate protection of lead or acrylic shields and disposal of radioactive wastes require shielded storage, long-term decay, or regulated landfill disposal. Most fluorescent molecules are easy to handle; the simple use of gloves affords adequate protection and disposal problems are minimal. As a consequence of its several distinct advantages, fluorescent labeling is in many cases less expensive than radiolabeling. Fluorescence labeling is a powerful tool to obtain information from chemical and biochemical systems for a variety of experimental, analytical, and quality control applications, several of which are described below.

### Labels and Reactions

In general, a label is a molecule capable of emitting a signal, which is designed for labeling and to localize

a specific region of a biological system, or to respond to a specific stimulus. It contains a signaling unit (the fluorophore), an anchor group for bonding to the molecule to be labeled, and a spacer. The signaling moiety acts a signal transducer, i.e., changes in the photophysical characteristics of the fluorophore due to different processes (e.g., energy transfer, polarization) are expressed as optical signals. As regards the spacer, it minimizes undesirable steric interactions between the signaling unit of the label and the labeled molecule. A substance labeled in this way is usually designated as a tracer.

The label must fulfill some specific requirements to be useful for labeling:

- Coupling to the target molecule must be simple and gentle to perform, specific for the compound of interest, fast, and quantitative. It is important also that the fluorescence of the label should be soluble in aqueous solutions and should be insensitive to environmental pH and polarity. Primary amines, thiols, and aldehydes are common functional groups available for biomolecules to covalently attach fluorescent labels.
- The label should not alter the properties of the target molecule or the functions of the cell or the organelle by reacting with key groups in active sites or by causing nonspecific binding of a labeled protein, or by causing steric perturbations because of its size. The probe should also not be phototoxic.
- The labeled compound should be stable and not undergo rapid decomposition.
- The luminescent properties of the label should not change significantly after the coupling.
- The labeled compound should have high fluorescence efficiency for maximum sensitivity. So, the value of molar extinction coefficient among fluorescent probes of current practical importance is  $\sim 5000 \text{ mol l}^{-1} \text{ cm}^{-1}$  to  $2 \times 10^5 \text{ mol l}^{-1} \text{ cm}^{-1}$ . On the other hand, for practical purposes, the quantum yield should be  $\sim 0.4$  or greater once the fluorescent probe is bound to the target and is in the solvent environment, where the measurement is to be made.
- Biological systems (e.g., proteins, cells) excited at wavelengths below 500 nm produce considerable autofluorescence that arises mainly from flavins, flavoproteins, NADH, etc. Labels that can be excited at wavelengths above 500 nm are much less susceptible to optical interference from biological chromophores in the test sample.

The term 'probe' is normally used as a synonym of label. Thus, in contrast to labels, probes respond to their microenvironment or to a chemical species. Those probes responding to a chemical species such as oxygen, an ion, or to pH are also referred to as indicators. In this article, both terms will be used indistinctly. Different classes of fluorescent labels are available. Low molecular weight dyes include xanthene (rhodamines, fluoresceins), cyanine, coumarins, sulfonated pyrenes, and metal phthalocyanine compounds, while high molecular weight labels include phycobiliproteins and other luminescent proteins.

## Intercalative Fluorescent Labels

Labeling is usually performed by the formation of a covalent bond between the fluorescent label and the target molecule. However, fluorescent dyes without a reactive group can be employed for some purposes. Due to their particular structural nature, fluorescent probes can bind noncovalently to special biomolecules in cells in a specific or a nonspecific fashion. In this case, the term 'stain' is used to refer to the label and 'staining' to the noncovalent attachment of the label to the studied object. There are a large number of fluorescent dyes that bind to DNA and RNA forming complexes via intercalation. Intercalating dyes are planar aromatic cations that insert between stacked base pairs on the DNA duplex. Their structure and chemical properties provide appropriate size and van der Waals interactions favorable for insertion between bases.

Intercalation provides an environmentally dependent fluorescence change, giving rise to a large fluorescence signal increase relative to the free dye in solution. This signal enhancement provides a concentration proportional response, allowing direct quantitative DNA measurements. Intercalating dyes can also bind nucleic acids inside whole cells, correlating the fluorescence response to enumeration and identification. Ethidium bromide (2,7-diamino-9-phenyl-10-ethylphenanthridinium bromide), related phenanthridinium dyes, and other intercalative dyes (Figure 1) illustrate the pattern of dye-nucleic acid interactions. The primary, intercalative mode of dye binding depends on double-helical polynucleotide structure. Such binding, which is associated with a shift in dye absorption from 480 nm to 520 nm and a marked increase in fluorescence efficiency, can occur with either DNA or RNA. In addition to intercalative binding, ethidium bromide can undergo an external electrostatic interaction with double helices. This secondary dye binding, which tends to reduce the

fluorescence quantum yield and lifetime of dye bound to primary sites, can be reduced by working in solutions of moderate ionic strength and low excess dye concentrations. Intercalative ethidium bromide depends little on nucleic acid base composition.

Important information about structural and functional aspects of DNA can be obtained from intercalative fluorescent dyes. For example, conformational factors, such as the presence of Z-DNA or superhelical DNA may affect dye binding, particularly for those intercalating dyes sensitive to topological constraints. Propidium iodide is not appreciably taken up by living cells, so this dye has been useful in discriminating live from dead cells. In contrast, certain bisbenzimidazole dyes, such as Hoechst 33342, are taken up by living cells and have become important fluorescent dyes for staining live cells. Dyes such as Hoechst 33258 preferentially bind to DNA regions that are rich in A-T base pairs while Chromomycin A<sub>3</sub> binds to regions that are rich in G-C. On the contrary, quinacrine and anthracene dyes have little base preference in binding, but their fluorescence quantum yield varies with base composition. The main limitation of intercalating dyes is their toxic/carcinogenic characteristics.

Fluorescence-based methods can detect nucleic acids in solution at concentrations in the nanogram per milliliter range and can be achieved using dyes such as PicoGreen for double-stranded DNA, OliGreen for single-stranded DNA and oligonucleotides, and RiboGreen for RNA. Usually, RNA samples must be treated with Dnase in order to remove DNA contamination as no dye is yet available that exhibits fluorescent enhancement specifically by binding to RNA. In Table 1, fluorescence characteristics of some common nucleic acid probes are summarized.

## Covalent Binding

For covalent labeling processes a few reactions have achieved practical significance. Primary amines, thiols, aldehydes, and ketones are common functional groups available for biomolecules to covalently attach fluorescent labels. In Figure 2, primary amine reactive groups and their reactions are shown. Amine-reactive labels are widely used to modify biomolecules and to prepare bioconjugates for immunochemistry, fluorescence *in situ* hybridization, receptor labeling, fluorescent analog cytochemistry, and cell tracing. Isothiocyanates are widely used to label proteins to form thiourea derivatives for fluorescence microscopy and fluorescence immunoassays. There are a number of amine-reactive fluorescent isothiocyanate labels, among which fluorescein isothiocyanate and tetramethylrhodamine

isothiocyanate are widely used for preparing fluorescent antibody conjugates. The *N*-hydroxysuccinimide ester group has several advantages over other reactive groups: (1) it can be readily synthesized from

carboxylic acid derivatives; (2) the corresponding labels can be obtained in high purity, so labeling can be a reproducible process; (3) the dry reagent can be stored for long periods of time without loss of

**Figure 3** Thiol fluorescent reactive labels (L, label; T, target).

**Figure 4** Carbonyl reactive groups (L, label; T, target).

## Molecular Beacons

Molecular beacons are oligonucleotide probes that contain both fluorophore and quencher moieties and can report the presence of specific nucleic acids in homogeneous solutions. First reported by Tyagi and Kramer in 1996, molecular beacons appear to be an invaluable tool for quantitative genomic studies. These probes possess a loop and stem structure (hairpin-shaped molecules), as schematically shown in **Figure 5**. The stem is formed by the annealing of complementary arm sequences on the ends of the probe sequence. A fluorescent moiety (e.g., tetramethylrhodamine, 5-iodoacetamidofluorescein) is attached to the 5'-end of the oligonucleotide and a quenching moiety (e.g., DABCYL, 4-(4'-dimethylaminophenylazo)benzoic acid) to the group at its 3'-end. The stem keeps these two moieties in close proximity to each other, thus causing the emission of the fluorophore to be quenched by energy transfer (direct fluorescence energy transfer or resonance energy transfer). When a target DNA hybridizes to

a molecular beacon, the conformational reorganization forces the stem apart and causes the fluorophore and the quencher to move away from each other, so the fluorophore is no longer quenched and the molecular beacon fluoresces. Molecular beacon technology can be used in a variety of PCR applications, for the detection of genetic mutations, to assay enzymatic cleavage of ssDNA (see **Figure 5**), and for RNA detection in living cells.

## Visible-Near-Infrared Labels

Fluorescein and rhodamine dyes have been for many years the dyes of choice in fluorescence labeling. These dyes belong to the xanthene class of dyes containing an oxygen atom in a central six-member ring. The fluorescence of fluorescein is pH sensitive and bleaches rapidly, thus limiting its use in many applications. Efforts to obtain more photostable fluorescent labels that can be excited in the long-wave region and also emit revealed that bioconjugatable

**Figure 5** Schematic representation of a molecular beacon.

**Figure 6** Visible–NIR labels.

arylsulfonated cyanine fluorophores, 4-bora-3a,4a-diaza-s-indacene-based fluorophores and tetramethyl-rhodamines and julolidine-based rhodamines include molecules that possess absorption and

emission maximums in the visible–near infrared (NIR) region of the spectrum (**Figure 6**) and are not affected by changes in pH between 4 and 10. These dyes find many uses in fluorescence microscopy,

**Table 2** Fluorescence characteristics of some NIR dye labels

immunodiagnostics, in whole-body imaging, and microarray analysis.

Cyanine-based dyes have a number of advantages over other dyes: the high molar extinction coefficient combined with a good quantum yield results in a very good brightness, which gives high sensitivity and direct labeling capability. Also, the addition of  $-\text{C}=\text{C}-$  units to the methine bridge between the two heterocyclic ring leads to a shift of  $\sim 100$  nm per unit in the excitation wavelength, leading to a wide range of multicolor dyes. The cyanines and related compounds, merocyanins, oxonols, and styryls, have high photostability, bind by intercalating between the bases of nucleic acid molecules, and are not pH sensitive. In Table 2 are reported the fluorescence characteristics of some commonly used cyanine, phenanthridine, and acridine NIR labels. These dyes found interesting applications in DNA microarray technology to investigate global changes in gene expression of cells and tissues.

Most bright fluorophores have usually small Stokes shifts and narrow absorption and emission bands and, consequently, cannot be used in combination with single laser lines for multicolor detection. A technique to provide fluorescent labels with large Stokes' shifts makes use of 'energy transfer cassettes'. In this approach a conjugate of a fluorescent donor (sensitizer) is covalently linked to a fluorescent acceptor. In the design of such constructs an inert, covalent linker between the donor and the acceptor holds the two dyes in close proximity, in such a way that efficient energy transfer from one dye to the other takes place when contiguous dyes are oriented parallel to each other, as opposed to any other arrangement. The overall Stokes' shift is dependent upon the wavelength of excitation of the donor fluorophore and the wavelength of emission of the acceptor one. Using cyanine dyes as both donor and acceptor molecules, a range of energy transfer cassettes has been synthesized. The labels used are the activated *N*-hydroxy-succinimidyl ester, maleimide, or other more specific labeling groups.

The multichromophore phycobiliproteins represent an additional series of labels that exhibit far-red absorption. Phycobilisomes are protein assemblies in cyanobacteria (blue-green algae) and red algae that enable them to harvest light that is not absorbed efficiently by chlorophyll, serving as light-absorbing antennae to funnel excitation energy into the reaction centers of photosystem II. The structures of the two prosthetic groups are given in Figure 7 and spectral data in Table 3. These proteins contain covalently linked tetrapyrrole groups that play a biological role in collecting light and, through fluorescence resonance energy transfer, conveying it to a special pair of chlorophyll molecules allocated in the photosynthetic reaction center. The compounds exhibit very high molar extinction coefficients ( $2 \times 10^6 \text{ mol l}^{-1} \text{cm}^{-1}$ ) and high quantum yields up to 0.98. Other several advantages of phycobiliproteins as fluorescent labels include: very high water solubility, multiple sites for stable conjugation to many biological and synthetic materials, relatively free of spectral interference from other biological materials, and a homogeneous structure with defined molecular weights. They were initially employed in fluorescence microscopy and thereafter methods were developed for flow cytometry and for coupling these large protein-chromophore complexes to antibodies studies. Conjugates of phycobiliproteins with other proteins is generally carried out using pyridyldisulfide derivatives, which can be directly reacted with thiolated antibodies, enzymes, and other biomolecules to form a disulfide linkage.

## Green Fluorescent Protein

Green fluorescent proteins (GFPs) are found in a variety of bioluminescent organisms such as the jellyfish *Aequorea victoria* and the anemone *Discosoma*. While most of other proteins require a cofactor to fluoresce, GFPs exhibit intrinsic fluorescence thanks to three amino acids that cyclize

**Figure 7** Phycobiliproteins.**Table 3** Spectral data of selected phycobiliproteins

Protein	Molecular weight ( $\times 10^{-3}$ )	Absorption maximum (nm)	Emission maximum (nm)	Molar extinction coefficient ( $\text{mol l}^{-1} \text{cm}^{-1}$ ) ( $\times 10^{-4}$ )	Fluorescence quantum yield
B-phycoerythrin	240	546, 565	575	240	0.98
R-phycoerythrin	240	496, 546, 565	578	200	0.82
Allophycocyanin	104	650	660	70	0.68

(Ser<sub>65</sub>-Tyr<sub>66</sub>-Gly<sub>67</sub>) and then undergo an oxidation step during a complex process of maturation. This fluorophore (see **Figure 8**) is tightly packed within the hydrophobic core of GFP that consists of a compact barrel of 11  $\beta$ -sheets with a central  $\alpha$ -helix containing the fluorophore.

GFPs are excellent markers for studying the expression and functional dynamics of proteins in real time in living cells using fluorescence methods such as photobleaching and chemical labeling with different colors of biarsenic compounds. For example, in fluorescence recovery after photobleaching (FRAP), GFP-tagged proteins within a specific region of a cell are photobleached using a high-power laser. The rate at which fluorescence recovers in the bleached region is related to the ability of nonbleached proteins to

move back into that area. This approach has been successfully applied to study protein dynamism in the Golgi region and the nucleus.

As wild-type GFPs are not optimal for some reporter-gene applications, genetically modified fluorescence-enhanced GFP variants, cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP) have been generated in order to overcome the weak emission intensity of wild GFP and some photochemical drawbacks. The adequate Stokes' shift of these proteins (CFP,  $\lambda_{\text{ex}}=434 \text{ nm}$ ,  $\lambda_{\text{em}}=477 \text{ nm}$ ; YFP,  $\lambda_{\text{ex}}=514 \text{ nm}$ ,  $\lambda_{\text{em}}=527 \text{ nm}$ ) and the possibility of efficient energy transfer from CFP to closely apposed YFP chromophores made them particularly useful for studying simultaneous protein expression, protein-protein interactions, and localized enzyme activation.

**Figure 8** Green fluorescent protein fluorophore and its environment.

**Figure 9** Chameleon calcium reporter.

Recently, a 'chameleon calcium reporter' has been designed by R.Y. Tsien to sense calcium in cells by FRET. The structure of the system is based on a CFP separated from an YFP by the calmodulin calcium binding protein (CaM) and a calmodulin binding peptide (M13). If  $\text{Ca}^{2+}$  ions are bound, CaM wraps around M13 allowing high efficiency of excitation transfer from the donor CFP to the acceptor YFP (see **Figure 9**). The degree of FRET in chameleon is a sensitive ratiometric reporter (ratio 527/434 YFP/CFP) of the calcium concentration in cells and in solution. The beauty of this approach is that the

reporter does not have to be loaded into the cell under study but the organism is transfected with gene so that all cells within the organism will express the calcium fluorescent indicator.

## Enzyme Labels

The first alternative to radioactive labeling was addressed using enzymes as labels. Although enzymes are no signal-generating compounds, they can produce many signal-generating species. The three more

**Figure 10** Fluorogenic enzyme substrates.

important enzymes that are commonly used as labels are alkaline phosphatase (AP),  $\beta$ -D-galactosidase (GAL), and horseradish peroxidase (HRP). Among them, HRP with a molecular weight of  $\sim 40$  kDa, presents the fewest labeling steric problems and AP displays the highest catalytic activity. The coupling of enzymes to antibodies or to other biomolecules is often achieved by bifunctional coupling reagents. On the other hand, fluorogenic enzyme substrates are compounds that are converted by specific enzymes into products that have either increased fluorescence or shifted spectra. Several fluorogenic enzyme substrates, many of them applicable to various hydrolytic enzymes, including esterases, phosphatases, and peptidases, are presented in **Figure 10**. In the listing chemiluminescent enzyme substrates such as luminol or dioxetane derivatives were not included. The principle of excited-state energy transfer can also be used to generate fluorogenic substrates; for example, when a donor fluorophore is effectively quenched by a nearby acceptor. The enzymatic cleavage of the substrate results in spatial separation of the fluorophore and acceptor, thus restoring the fluorophore's

emission (see **Figure 11**). The donor and acceptor must be carefully chosen to ensure efficient quenching through excited-state energy transfer. The use of fluorogenic enzyme substrates has been particularly useful for monitoring enzyme activities and in situations where enzyme activities are low.

## Fluorescent Labeling Based on Substituent Effects

Some reactions used for fluorescence labeling are based on changing the nature of a substituent on an aromatic structure. For example, the reaction of fluorescamine with amines is quite similar to a labeling reaction, is fast, and specific for primary amines. The reagent itself is not fluorescent and does not hydrolyze to a fluorescent product. Reaction of cyanide with benzoquinone is another example where modification of a substituent eliminates  $n - \pi^*$  transitions into the basic aromatic structure. Addition of an electron-donating substituent results in a modification of fluorescence properties, such as in the

**Figure 11** Enzymatic suppression of fluorescence energy transfer.

reaction of primary or secondary amines with 1,2-naphthoquinone-4-sulfonic acid. Some of these fluorescence labeling reactions are summarized in Figure 12.

## Labeling Based on Metal Centered Dyes

The use of conventional fluorophores in biological fluids and samples may lead to serious limitations in sensitivity due to the natural fluorescence from proteins and other matrix compounds present. Several lanthanoid fluorescent chelates have spectrochemical features that typical fluorophores do not have: long lifetimes exceeding 1 ms in some cases, large Stokes shifts (over 250 nm), and very sharp peak profiles. The background signals from biological samples being short-lived, the binding of lanthanoid labels to proteins, nucleic acids, and many other molecules, and the use of time-resolved fluorescence techniques may reduce prompt fluorescence interferences.

As the emission of radiation occurs from the lowest state of the lanthanide metal ion the chelator must have an excited triplet state with an energy level higher than the lowest emissive level of the metal.

Fluorescent lanthanoid chelates absorb radiation at the wavelength characteristic of the chelator and emit with the wavelength characteristic of the metal, due to energy transfer from the ligand to the metal ion. Lanthanoid chelates are mainly based on bipyridine, polyaminocarboxylate, and cryptate chelators. A typical antenna attached to some polyaminocarboxylate chelators is carbostyryl 124 (7-amino-4-methyl-2(1*H*)-quinolinone) (see Figure 13), which absorbs at a wavelength of 337 nm and the main emission will be at 615 nm for europium and 543 nm for terbium.

Europium and terbium chelates acting as donors offer many technical advantages: (1) the efficiency of energy transfer is considerably higher compared to conventional fluorescent donors, leading to larger signals and longer measurable distances; (2) because lanthanide chelate emission is generally unpolarized, energy transfer is not dependent on their relative orientation but on the distance between donor and acceptor; (3) due to the long-lived fluorescence, lifetime measurements can be made with high precision; (4) the system can provide highly sensitive detection limits by two to four orders of magnitude relative to those of conventional techniques; (5) the sensitized emission of the acceptor due to energy transfer can

**Figure 12** Fluorescent labeling based on substituent effect.

**Figure 13** Fluorescent metal chelates used as labels.

be measured because it is being fed in by the long-lived lanthanide chelate donor; (6) the ligand field around the metal center prevents quenching by water molecules and the consequent nonradiative loss of energy; (7) photobleaching resistance.

Due to their long lifetime of emission and their spectral properties lanthanide complexes are used in time-resolved fluorescence techniques as well in FRET and time-resolved FRET assays. Acceptors can be conventional organic fluorophores, so the emission is dominated by the acceptor spectral characteristics. Coupling of lanthanide chelates to biomolecules can be carried out using thiol-, amine-, ATP-binding reactive derivatives. Lanthanoid fluorescent chelate labels have been used for to explore processes where distance relationship or supramolecular structures are involved: protein associations, immunoanalysis, nucleic acid hybridization, and DNA polymerase reactions. New potential applications are envisaged, including screening of libraries from automated peptide and combinatorial chemical synthesis.

In addition to lanthanide chelates, metalloporphyrins form another class of potentially interesting fluorescent (and phosphorescent) labels. Their luminescence properties depend on the metal substitution, Pt- and Pd-substituted complexes being the most useful. These labels have high molar extinction coefficients (generally above  $1.5 \times 10^5$ ), lifetimes in the range 1–100  $\mu$ s, and exhibit absorption maximum at  $\sim 400$  nm and long wavelength fluorescence emission maximum above 600 nm. The Pd and Pt complexes have also high phosphorescence quantum yield, even in an aqueous environment at room temperature. Metalloporphyrins are chemically and photochemically stable compounds and proved to be useful for time-resolved fluorescence microscopy as labels for antibodies and (strep)avidin.

## Fluorescent Derivatization Based on Metal Complex Formation

Metal complex formation may cause a nonfluorescent structure to become fluorescent, thus allowing the determination of either metal ion or organic compounds. The process involves the change of  $n - \pi^*$  lowest excited singlets in noncomplexed organic compounds to  $\pi - \pi^*$  lowest excited singlets upon complexation. In Figure 13, a listing of the most widely used reagents is shown. A lot of work has been done in this field with the aim to improve the selectivity for particular metal ions determination, from the synthesis of new reagents to the use of solvent-solvent extraction, and of ordered media

(micelles, cyclodextrins) to protect singlet excited states. For example, during the last decade or so, a number of fluorescent labels have been designed for the analysis of intracellular important metal ions like  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Zn}^{2+}$ , and others. These fluorescent compounds are variations of the nonfluorescent caged chelators EGTA (ethylene glycol-bis-(2-aminoethyl)- $N,N,N',N'$ -tetraacetic acid) and BAPTA (1,2-bis(*o*-aminophenoxy)ethane- $N,N,N',N'$ -tetraacetic acid) and fluorescent signaling units (rhodamine, aminonaphthalene), which combine the metal binding ability with advantageous chemical/photochemical properties. There are many of these fluorescent probes commercially available (fura-2, indo-1, quin-2, fluo-3, rhod-2, etc.) as salt, acetoxymethyl ester, or dextran forms. Salt and dextran forms are typically microinjected or scrape loaded into cells while the ester derivatives are cell membrane permeant. These derivatives are converted by cellular esterases into the free-acid impermeant form of the dye. The trapped dye is then able to chelate the metal ion (e.g., calcium, magnesium). The fluorescence enhancement and/or the luminescence spectral shifts upon metal binding are used for detecting the metal ion concentration and for imaging the ion levels by fluorescence imaging microscopy with high sensitivity and selectivity.

Some metal ions do not form fluorescent complexes due to their paramagnetic nature (e.g.,  $\text{Fe}^{3+}$ ,  $\text{Co}^{2+}$ ) or due to the heavy atom effect (e.g.,  $\text{Pb}^{2+}$ ,  $\text{Hg}^{2+}$ ) both of which promote intersystem crossing, thus deactivating the excited singlet. While fluorescence methods for metal ions are highly sensitive and have wide linear dynamic ranges, the Achilles' heel of the approach is the lack of selectivity, thus making competing techniques such as atomic absorption and inductively coupled plasma the methods of choice. In contrast, it is possible to analyze nonfluorescent organic compounds by forming fluorescent complexes with metal ions. Although this approach offers analytical potential for the analysis of nonfluorescent aromatic compounds, relatively little attention has been paid to it. Typical examples of this approach include the fluorescent analysis of antibiotics and vitamins (e.g., anthracyclines) (Figure 14).

## From Solution Labels to Microarray

During the last 15 years there has been a renaissance of fluorescence, mainly driven by: (1) recent advances in fluorescence detection techniques; (2) the availability of powerful data acquisition and data analysis systems; (3) the development of an array of improved fluorescent dyes and labels; and (4) the increasing

**Figure 14** Fluorescent metal complex formation.

demand for understanding the fundamental principles behind life sciences, specially in genetics, proteomics, molecular, and cell biology. The present account illustrates the great variety of fluorescent labeling approaches that are possible for obtaining chemical and biochemical information. Although not specifically addressed in this article, a wide range of physical and photophysical parameters (fluidity, membrane potential, viscosity, polarity, dielectric constant, lifetime, quantum yields, excited states energy) are also measurable, given the appropriate environmental sensitive fluorescent probe (e.g., 1-anilino-8-naphthalene sulfonate, pyrene, 7-alkoxycoumarin, 6-propionyl-2-(dimethylamino)naphthalene), and using diverse fluorescence techniques such as steady-state methods, time-resolved fluorescence polarization, fluorescence quenching, excimer formation, or energy transfer.

Fluorescence labeling provides a powerful tool for the selective and sensitive determination of a plethora of chemical and biochemical species in a variety of conditions, including live cells, in real time. Immobilization of a fluorescent label on a solid support, such as microparticles or beaded polymer resins, have found interesting applications in the

development of fluorescent optical sensors, in flow-cytometric analysis, in fluorometric microvolume assays, for testing of multiple analytes in one reaction, and high-throughput screening approaches (sensor arrays). For small molecules or short peptides, immobilization often requires covalent linkage of the compounds onto the solid support, while for larger molecules binding may be accomplished by either covalent linkage or noncovalent adsorption. Covalent attachment by methods as those described above is conventionally used. For instance, amine-containing small molecules or proteins can be covalently attached to aldehyde derivatized glass slides to form Schiff's base linkages. Thanks to the possibility of immobilizing thousands of small molecules, peptides, and/or proteins in a small area on a solid-support, to the quality of the chemical chips, and the instrumentation, chemical microarray technology using fluorimetric detection methods has resurfaced as a popular research approach, especially in the fields of genomics and proteomics. It is expected that the development of new ways of introducing fluorescent labels into solid support, particles, proteins, and other biological molecules and the continued development of new enhanced fluorimetric probes

will further expand the applicability of fluorescence techniques and chemical microarray into inexpensive and highly efficient medical diagnostics and environmental monitoring tools in the future.

## Introduction

Fluorescence analysis methods are now widely used because of their extreme sensitivity, which provides detection limits at picomolar levels and below, and the great variety of sample presentation methods available. Flowing liquids, solid surfaces, concentrated solutions, and suspensions can all be studied in addition to measurements in dilute solution. This article is concerned with the quantitative relationships underpinning steady-state fluorescence measurements: time resolved fluorescence is considered separately.

## Quantitation in Dilute Solution

Since the absorption of photons is the primary process in a fluorescence experiment, the starting point for quantitative studies must be the Beer–Lambert law. For a single absorbing solute, this takes the form:

$$\log_{10} \frac{I_0}{I_t} = \epsilon bc = A \quad [1]$$

Here  $I_0$  and  $I_t$  are, respectively, the intensities of light incident on the sample and transmitted by the sample,  $\epsilon$  is the molar absorptivity of the solute (with units of  $\text{l mol}^{-1} \text{cm}^{-1}$ ),  $b$  is the optical path length in

the sample cell (cm), and  $c$  is the molar concentration of the solute ( $\text{mol l}^{-1}$ ). The product  $\epsilon bc$  is the absorbance,  $A$ , of the sample. This equation can be re-written:

$$I_t = I_0 10^{-\epsilon bc} \quad [2]$$

In fluorescence experiments, interest lies in the amount of light absorbed,  $I_a$ . If the assumption is made that all the light not transmitted is absorbed (i.e., scattered and stray light phenomena are ignored):

$$I_a = I_0 - I_t = I_0(1 - 10^{-\epsilon bc}) \quad [3]$$

Only a fraction of the molecules electronically excited by the absorption of photons subsequently emit fluorescence photons. This fraction is known as the quantum yield,  $\phi_f$  ( $0 \leq \phi_f \leq 1$ ). The intensity of fluorescence,  $I_f$ , is thus given by:

$$I_f = I_a \phi_f = I_0 \phi_f (1 - 10^{-\epsilon bc}) \quad [4]$$

Expansion of this equation gives:

$$I_f = I_0 \phi_f \left\{ 1 - \left( 1 - 2.303 \epsilon bc + \frac{(2.303 \epsilon bc)^2}{2!} - \frac{(2.303 \epsilon bc)^3}{3!} + \dots \right) \right\} \quad [5]$$

If the absorbance,  $\epsilon bc$ , is small – say, less than 0.02 (see below) – then all the terms in the expansion after  $-2.303 \epsilon bc$  are assumed to be negligible, giving:

$$I_f = 2.303 I_0 \phi_f \epsilon bc \quad [6]$$

will further expand the applicability of fluorescence techniques and chemical microarray into inexpensive and highly efficient medical diagnostics and environmental monitoring tools in the future.

## Introduction

Fluorescence analysis methods are now widely used because of their extreme sensitivity, which provides detection limits at picomolar levels and below, and the great variety of sample presentation methods available. Flowing liquids, solid surfaces, concentrated solutions, and suspensions can all be studied in addition to measurements in dilute solution. This article is concerned with the quantitative relationships underpinning steady-state fluorescence measurements: time resolved fluorescence is considered separately.

## Quantitation in Dilute Solution

Since the absorption of photons is the primary process in a fluorescence experiment, the starting point for quantitative studies must be the Beer–Lambert law. For a single absorbing solute, this takes the form:

$$\log_{10} \frac{I_0}{I_t} = \epsilon bc = A \quad [1]$$

Here  $I_0$  and  $I_t$  are, respectively, the intensities of light incident on the sample and transmitted by the sample,  $\epsilon$  is the molar absorptivity of the solute (with units of  $\text{l mol}^{-1} \text{cm}^{-1}$ ),  $b$  is the optical path length in

the sample cell (cm), and  $c$  is the molar concentration of the solute ( $\text{mol l}^{-1}$ ). The product  $\epsilon bc$  is the absorbance,  $A$ , of the sample. This equation can be re-written:

$$I_t = I_0 10^{-\epsilon bc} \quad [2]$$

In fluorescence experiments, interest lies in the amount of light absorbed,  $I_a$ . If the assumption is made that all the light not transmitted is absorbed (i.e., scattered and stray light phenomena are ignored):

$$I_a = I_0 - I_t = I_0(1 - 10^{-\epsilon bc}) \quad [3]$$

Only a fraction of the molecules electronically excited by the absorption of photons subsequently emit fluorescence photons. This fraction is known as the quantum yield,  $\phi_f$  ( $0 \leq \phi_f \leq 1$ ). The intensity of fluorescence,  $I_f$ , is thus given by:

$$I_f = I_a \phi_f = I_0 \phi_f (1 - 10^{-\epsilon bc}) \quad [4]$$

Expansion of this equation gives:

$$I_f = I_0 \phi_f \left\{ 1 - \left( 1 - 2.303 \epsilon bc + \frac{(2.303 \epsilon bc)^2}{2!} - \frac{(2.303 \epsilon bc)^3}{3!} + \dots \right) \right\} \quad [5]$$

If the absorbance,  $\epsilon bc$ , is small – say, less than 0.02 (see below) – then all the terms in the expansion after  $-2.303 \epsilon bc$  are assumed to be negligible, giving:

$$I_f = 2.303 I_0 \phi_f \epsilon bc \quad [6]$$

In practice, however, only a small fraction,  $K$ , of the emitted photons is detected in most instruments, so this extra term should be included in the equation for the measured fluorescence:

$$I_f = 2.303I_0\phi_f K\epsilon bc \quad [7]$$

This equation deserves close study. High fluorescence intensities depend on the solute having a high molar absorptivity,  $\epsilon$ , as well as a high quantum yield,  $\phi_f$ . The product  $\epsilon\phi_f$  has been used as a measure of the sensitivity of a solute in fluorescence work, though in reality much will depend on the wavelengths of excitation and emission, the Stokes shift (see below), and the instrumentation used. Two solutes with similar  $\epsilon\phi$  values will not necessarily have similar limits of detection if their excitation and emission wavelengths are different. Fluorescence intensity is also proportional to the incident light intensity, so light sources should be bright and stable. However, most solutes suffer from photodecomposition to a greater or lesser extent, and in practice limits of detection are usually controlled by background signals (see below), so the use of brighter light sources will not be beneficial *ad infinitum*. Anything that can be done to increase the light collection factor  $K$  is beneficial. Finally, the equation shows that the fluorescence intensity should be proportional to concentration, which is obviously desirable when establishing calibration plots for quantitative analysis.

In practice, when fluorophore solutions of increasing concentration are studied the calibration plot will be similar to that shown in Figure 1. At low concentrations the fluorescence intensity is proportional to the concentration as expected, but at higher concentrations negative deviations from linearity occur, and eventually the curve may 'roll over'. The latter effect only occurs at such high levels that it is unlikely that an error would be made in using the

**Figure 1** Typical relationship between fluorescence intensity and concentration for a single fluorophore in solution.

graph to estimate concentrations in a calibration experiment, but the reasons for the lack of linearity demand examination. There are three distinct explanations for a nonlinear response.

The first factor is the mathematical approximation involved in deriving eqns [6] and [7]. If the absorbance of the sample at the excitation wavelength used is, for example, 0.02, then in eqn [5] the term  $2.303\epsilon bc$  has a value of 0.04606. The next term,  $-(2.303\epsilon bc)^2/2!$ , has a value of  $-0.00106$ , i.e., it reduces the effect of the first term, and thus the fluorescence intensity, by  $\sim 2.3\%$  although it is ignored in eqns [6] and [7]. Similarly, if the absorbance reaches 0.05, the corresponding error is  $(- )5.5\%$ . In fluorescence measurements in a 1 cm cuvette the relative standard deviation of replicate intensities for the same sample is commonly about 2%. This figure can be improved substantially by the use of a constant temperature (see below), extreme cleanliness, and care in positioning the cuvette in the light beam (e.g., always using the same faces of a single cuvette). Better repeatability is also usually obtained in the detection of flowing liquids, e.g., in flow injection analysis. It is therefore recommended that the absorbance of the sample at the excitation wavelength should not exceed 0.02, more concentrated samples being diluted if necessary. This is not a serious drawback to the technique. A solute having a relative molecular mass of 500 and a molar absorptivity,  $\epsilon$ , of  $10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$ , gives an absorbance of 0.02 in a 1 cm cuvette at a concentration of  $1 \mu\text{g ml}^{-1}$ . Most fluorescence analyses are performed at concentrations well below this level, so the upper limit on the absorbance value is not of concern.

However, the absorbance of a sample also has an important bearing on inner filter effects, which in practice are the major causes of curved fluorescence calibration plots. Inner filter effects arise for the reasons summarized in Figure 2. In most instruments light from the exit slit of the excitation monochromator falls directly on to the cuvette, in some cases with the aid of a focusing lens. The result is that the beam illuminating the sample is much narrower than the cuvette itself. (For simplicity, this light beam is assumed to be parallel in Figure 2.) Similarly, the entrance slit of the emission monochromator effectively interrogates only a narrow section of the cuvette, at right angles to the illuminated region. So fluorescence is only excited and observed in a small central region of the cuvette. This arrangement has some merits. For example, photodecomposed sample molecules may diffuse out of this region, to be replaced by fresh ones, thus reducing the measured effects of any photodecomposition phenomena. But its drawback is that optical artifacts can occur in the

**Figure 2** Origin of inner filter effects in solution fluorimetry. Exciting and emitting light beams intersect only in the center of the cuvette (shaded). Pre- and postfilter effects occur in regions X and Y, respectively.

regions of the cell marked X and Y. In region X, photons can be absorbed by the solute (or other sample components). The light intensity reaching the central region of the cuvette is thus reduced, and according to eqn [7] the fluorescence emitted is also reduced. If the absorbance of the sample at the excitation wavelength is very high few photons will reach the central region and little or no fluorescence will be seen: this is the cause of the 'roll-over' effect described above. In region Y, fluorescence photons emitted from the central region of the cuvette can be re-absorbed, either by other solute molecules (because the excitation and fluorescence spectra of a given material often overlap) or by other components of the sample. Again, the result is a reduction in the observed fluorescence. Equations have been derived that detail such effects, and they have even been used to estimate quantum yields (see below). In practice, however, it is much more important to minimize inner filter effects by ensuring that samples have low absorbances at the excitation and emission wavelengths in use.

Inner filter effects can also be reduced by minimizing the dimensions of the regions X and Y, either by using short pathlength cuvettes, or by off-setting the cuvette in the light beam so that its corner rather than its center is illuminated and observed by the instrument optics (**Figure 3**). These methods run the risk that the excitation or emission beams might strike the side-walls of the cuvette, increasing the scattered light interference. Flow cells used for high-performance liquid chromatography or flow injection detection normally have a short pathlength, and so do not show significant inner filter effects, but they have to be carefully matched to the optical characteristics of the instrument if this scattered light problem is to be avoided.

The third reason for negative curvature in fluorescence calibration graphs is the occurrence of

**Figure 3** Cuvette arrangements to minimize inner filter effects: (A) use of corner of the cuvette and (B) use of a short pathlength cuvette.

bimolecular processes. Many organic fluorophores are large planar molecules with extensive  $\pi$ -electron systems, and as their concentration increases they tend to aggregate through  $\pi$ - $\pi$  interactions. Such aggregates often have reduced or different fluorescence properties compared with the monomeric molecules. In particular, the formation of excimers (excited state dimers) with a rather weaker fluorescence at longer emission wavelengths than the monomers is quite frequently observed. This is an example of self-quenching, i.e., the reduction of the fluorescence of one molecule by another identical one. Such phenomena do not normally occur in very dilute solutions (though some long-wavelength fluorophores do aggregate even at sub-ppm levels), so a linear relationship between fluorescence and concentration would normally be expected for materials studied at sub-micromolar levels. Sadly, the effects described above are often poorly explained and named in the fluorescence literature. Inner filter effects are often referred to as self-quenching (though no molecule-molecule interactions are involved), and the mathematical approximation problem is sometimes called an inner filter effect, even when there is no such optical artifact present.

## Quantitation for Other Sample Types

Although fluorescence methods are frequently applied to the analysis of very dilute solutions, their uses with other sample types are often important. One example is the situation that arises when the concentration of the fluorescent solute is so high that virtually all the light in a given wavelength range striking the sample is absorbed. In that case the intensity of fluorescence emitted is independent of concentration. If the quantum yield and the emission spectrum of the fluorophore are independent of the excitation wavelength, the intensity of the emission is proportional to the intensity of the incident light, and the sample functions as a quantum counter. Such devices are used in spectral correction systems and other areas of photochemistry.

Fluorescence measurements on solid surfaces are extremely important, as the method is used for scanning thin-layer chromatography plates, zone electropherograms, solid-phase immunoassay media, etc. Room-temperature phosphorescence is also often observed at solid surfaces. The optical situation in such systems is more complex than that in dilute solution for several reasons. Emitted fluorescence can be detected in reflection or transmission modes; the solid phase may exhibit its own light absorption and/or fluorescence properties; solid-phase thickness and the presence of any backing material will affect the results; scattering and reflection of the incident light is substantial; and the angle of incidence of the exciting light beam is critical. It is therefore not surprising that in most theoretical studies simplifying approximations are made. For example, an angle of incidence of  $90^\circ$  and uniformity of the solid phase are commonly assumed. A number of equations have been derived by various authors, but there is general agreement that the signals emitted from a given illuminated area by low levels of fluorescent material are proportional to the amount of fluorophore present, and also proportional to the intensity of the incident light. (In these respects surface fluorescence and fluorescence from dilute solutions are similar.) The intensity of the reflected fluorescence is higher than that of the transmitted fluorescence, but the linear range will be poorer for the former than the latter.

### Limits of Detection in Fluorescence Spectroscopy

The ability of fluorescence methods to detect very low concentrations derives from the basic photochemistry involved in the measurement process. Fluorescence is emitted at longer wavelengths than that of the exciting light, and can be observed without serious interference from the latter. The detected signal is usually only a fraction of the total emitted fluorescence, but detecting it against a 'dark' background using the  $90^\circ$  optics of fluorescence spectrometers is critical to the attainment of low limits of detection. By contrast, absorptiometric measurements at trace levels rely on the detection of a small difference between two signals of similar high intensity, i.e., the signal reaching the detector when only the solvent blank is present, and the corresponding signal when low levels of analyte are present. A modern absorption spectrometer carefully used might detect an absorbance,  $A$  (or an absorbance difference), of 0.0001. For a solute with a high molar absorptivity,  $\epsilon$ , of  $10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$  this corresponds to a detection limit of  $10^{-9} \text{ mol l}^{-1}$  ( $1 \text{ nmol l}^{-1}$ ).

Theoretical estimates and experimental evidence agree that a fluorophore with this  $\epsilon$  value and a quantum yield,  $\phi_f$ , of 0.50 could be detected in a good fluorescence spectrometer at levels of  $1 \text{ pmol l}^{-1}$  or less: the fluorescence method gives limits of detection at least three orders of magnitude lower (better) than the absorption spectrometry method.

### Background Signals and Their Reduction

In practice, low limits of detection are only obtained if the background signal (i.e., the signal in the absence of the fluorophore) is as close to zero as possible. The limit of detection for a solute (determined by any methodology) is conventionally defined as the concentration that gives a signal three standard deviations above the background level (some authorities use a factor of two rather than three). In practice, as a solution of a fluorophore is progressively diluted and measured, there comes a point where the observed signal is not significantly different from the background. In such conditions instrumental sensitivity improvements such as the use of laser sources or photon counting detectors may be of no help. The background signal is often much worse with 'real' samples (blood plasma, urine, environmental materials, etc.) than with pure solutions of the fluorophore, and much attention has been paid to the need to minimize it by optical and/or chemical means. Similar problems arise in the analysis of fluorophore mixtures. Unless the excitation and/or emission wavelengths of the mixture components are well separated, analysis of one component will be complicated by background signals from the others. Some of the techniques used for background reduction are thus also applicable to mixture analysis.

A major potential source of background signals is scattered light. For materials in dilute solution Rayleigh scattering is the dominant phenomenon. It results from elastic photon-molecule collisions, so occurs at the same wavelength as the incident light. But fluorescence instruments conventionally use monochromators with pass-bands (measured at half-maximum intensity) of 5–10 nm, so when fluorophores with small Stokes shifts (emission minus excitation maximum wavelengths) are studied the possibility of interference is very real. A good example is the common fluorophore fluorescein, which has a Stokes shift of only  $\sim 23 \text{ nm}$  ( $\lambda_{\text{ex}} 490 \text{ nm}$ ;  $\lambda_{\text{f}} = 513 \text{ nm}$  at pH 9). Other widely used xanthine dyes suffer from the same problem, and many long-wavelength dyes have even smaller Stokes

shifts. Possible remedies include the use of polarizing filters (since Rayleigh scattered light is strongly polarized), or cut-off filters to supplement the performance of the emission monochromator. Probably the simplest remedy is to use an excitation wavelength that is suboptimal in terms of fluorescence intensity, but results in much reduced scattered light. For example, exciting fluorescein (pH 9) at  $\sim 480$  nm causes a loss of fluorescence intensity of 25% compared with the optimum wavelength of 490 nm. But the reduced scattered light signal in the emission beam might well more than compensate for this.

Scattering by the Raman mechanism is a very weak phenomenon in solution, so that only solvent Raman bands are observed, but they can nonetheless present a problem. For any solvent, Raman bands occur at a predictable frequency. The main Raman band of water is at  $\sim 3400\text{ cm}^{-1}$ , so for excitation wavelengths of (for example) 280, 350, and 490 nm, the corresponding Raman emissions are at 309, 397, and 588 nm, respectively. (The signal-noise ratio of the water Raman band excited at 350 nm is often used as a criterion of fluorescence spectrometer sensitivity.) Examples of problems caused by Raman scattering are studies of tyrosine and its derivatives in aqueous solutions, using an excitation wavelength of 280 nm. The water Raman band at 309 nm strongly overlaps with the tyrosine fluorescence at *c.* 307 nm (and Rayleigh interference may also occur). In this and other cases it is not usually possible to remove the effects of scattered light by running a blank and subtracting it from the sample fluorescence. Scattering is enhanced by the presence of proteins and other macromolecules in the sample, so it is impossible to provide a realistic blank. There should not be any confusion between Raman bands and fluorescence signals, partly because Raman shifts are predictable, and partly because of a simple test that will distinguish them immediately. Shifting the excitation wavelength by (say) 10 nm will cause a shift in the wavelength of the Raman band, but no shift in the wavelength of fluorescence, though the intensity of the latter may change. The intensities of Rayleigh and Raman scattered light become much less in the near-infrared region of the spectrum, as they vary as the inverse fourth power of the incident light wavelength. Moreover, the solvent Raman shifts in this region are very large in wavelength terms. Excitation of an aqueous solution at 650 nm produces a Raman band at 834 nm, in contrast with the very small Stokes shifts of typical long-wavelength fluorophores. This reduction of scattered light interference is one of the major reasons for the much increased use of long-wavelength fluorescent labels

in recent years. (Raman spectroscopists also favor working in the near-infrared region: there is reduced fluorescence background for their samples, as there are not many long-wavelength fluorophores.)

Solvents and other materials used in fluorescence measurements are further sources of background signals. Some water samples contain parts per billion levels of strongly fluorescent aromatic hydrocarbons and other fluorophores. These contaminants are not removed by conventional purification methods involving ion exchange, so extra purification steps are necessary. Organic solvents are even more prone to such interferences (many of them come originally from oil fractions). Some plastic materials give background fluorescence problems, from plasticizers or transition metal compounds used in polymerization processes. Careful choice of solvents and reagents, and extreme cleanliness and care in laboratory procedures are essential if the full sensitivity of fluorescence is to be achieved.

Many natural samples show strong 'autofluorescence' signals. The fluorescence of typical blood plasma specimens and of urine is well documented, for example. In some cases fluorescence analyses of components of such matrices are carried out only after a separation or extraction process, so that the final determination is performed on an essentially pure, or much purified, compound. In many applications (for example, in enzyme- and antibody-based assays) this is entirely impractical, so alternative methods of background reduction are used. Time-gated systems in conjunction with labels or probes based on long-lived fluorophores or phosphors are now common. The instrumentation involved is summarized in a separate article, and the principle is illustrated in **Figure 4**. The sample is illuminated with pulses of light 10–20  $\mu\text{s}$  long, and a gating electronics system allows the detector to start recording the emission after each light pulse has ended. Any fluorophore with a lifetime of  $\sim 100\mu\text{s}$  or more can thus be detected without background interference from the rapidly decaying scattered light and conventional fluorescence signals, the latter having typical lifetimes of only a few nanoseconds. This approach has encouraged the development of analytical methods based on the use of lanthanide ions or ruthenium complexes as labels.

The reduction of autofluorescence is another major reason (alongside the ready availability of suitable solid-state optical components) for the increased use of long-wavelength fluorescence. Fluorescent labels, probes, and enzyme substrates with excitation wavelengths in the 600–800 nm region, where there are very few naturally occurring fluorophores, provide methods with very low background signals.

**Figure 4** Use of time-gated detector system to minimize background effects in fluorescence. The detector does not respond during the delay time, but only during the gate time: by then the source pulse and the scattered light and prompt fluorescence resulting from it are not detected. The gate time ends before the next source pulse begins.

Other spectroscopic methods for background reduction include the use of derivative fluorescence spectra and synchronous scanning. Derivative spectra (the first or second derivatives are mostly used) are readily calculated using PC-interfaced spectrometers, and in principle offer a number of possibilities. For example, the fluorescence of one component in a two-fluorophore mixture can be studied without interference from the second component at the maximum fluorescence wavelength of the latter, where its first derivative spectrum has zero intensity. Synchronous scanning is described elsewhere: it produces simpler and narrower spectra with reduced overlap between signals from different fluorophores, and thus may also help in reducing background effects. The disadvantage of these approaches is that they require spectral scans of every sample, rather than measurements at a single pair of excitation and emission wavelengths. Scanning spectrometers or array detectors are thus essential, and each sample may take longer to analyze. In recent years, however, the use of diode array detectors with chemometric data handling (e.g., partial least squares) methods has allowed the rapid simultaneous analysis of two or more fluorophores, even when their emission spectra are very similar.

## Fluorescence Quenching Methods

Many analytical procedures have been developed in which the analyte is a quencher of the emission of a fluorescent reagent. One application area is the detection and determination of nitro compounds such

as carcinogenic nitro-aromatics, explosives. The detection of oxygen through fluorescence quenching in simple sensors is another important application. The quantitative aspects of such studies are quite different from those of other fluorescence measurements. The principal equation describing dynamic quenching processes (those in which the excited state of a fluorophore interacts with the quencher: is the Stern–Volmer equation:

$$\frac{\phi_0}{\phi} - 1 = k_Q \tau_0 [Q] \quad [8]$$

Here,  $\phi_0$  and  $\phi$  are the quantum yields of the fluorophore in the absence and presence, respectively, of the quencher  $Q$ ,  $k_Q$  is the quenching constant,  $\tau$  is the fluorescence lifetime of the fluorophore in the absence of the quencher, and  $[Q]$  is the quencher concentration. The product  $k_Q \tau_0$  is sometimes called the Stern–Volmer constant,  $k_{SV}$ . It has a typical value of  $\sim 100 \text{ l mol}^{-1}$  for conventional fluorophores in solution at room temperature. If a quenching effect of 1% is the smallest that could be detected, i.e.,  $(\phi_0/\phi - 1) = 0.01$ , then from [8] the lowest concentration of  $Q$  detectable is  $10^{-4} \text{ mol l}^{-1}$ . Some quenching interactions have been found with  $k_{SV}$  values significantly greater than 100 (e.g., using long-lifetime fluorophores or phosphors). In other cases arrays of dozens of individual sensors have been used, with signal processing methods applied to evaluate the modest quenching effects. But quenching analyses are evidently much less sensitive than conventional fluorescence methods. This is, of course, because all quenching methods rely on detecting a small reduction in a large fluorescence signal: in sensitivity terms they are thus analogous to absorption spectrometry methods.

## Other Quantitative Methods

Amongst the many applications of fluorescence several other quantitative approaches are used. Many types of immunoassay using fluorescent labeled antibodies or antigens have been developed. In some cases the intensity of fluorescence measured should be proportional to the amount of analyte present, but in others increasing analyte levels give rise to diminishing fluorescence signals. Moreover, fluorescence polarization may be measured rather than a straightforward intensity. Enzyme activities are often determined using fluorogenic substrates, non-fluorescent, or weakly fluorescent species converted by enzyme action to strongly fluorescent products. The presence of inhibitors will cause a loss of fluorescence intensity, so these materials can also be

determined. In all these analyses the use of constant temperatures is obligatory, as the activities of the biomolecules are temperature dependent, as are any fluorescence signals generated.

## Temperature Effects

The effects of temperature on the fluorescence of individual solutes have been studied repeatedly. In virtually all cases fluorescence intensities fall as the temperature rises, the higher frequency of bimolecular collisions and higher energy vibrational modes increasing the probability of nonradiative energy loss from excited molecules. The radiative properties of the excited state are also affected indirectly by temperature dependent changes in the refractive index of the solvent, and the latter influences the geometry of the fluorescence emitted from the sample cuvette. The absorbance of the sample is also likely to be affected by temperature changes, though to a less extent than the fluorescence quantum yield. It is to be expected that the effect of temperature on the latter might take an exponential form, and that it would become greater as the energy difference between the ground state and the first excited singlet state of the molecule decreases. Equations of the following form have been suggested:

$$\frac{1}{\phi_f} - 1 = k_1 e^{-E/RT} + k_2 \quad [9]$$

In this equation,  $k_1$  and  $k_2$  are constants and  $E$  is an activation energy related to both the structure of the solute and the viscosity of the solvent (which is also temperature dependent!). In practice, perhaps because of the numerous effects summarized above, the following results have been obtained:

- Over limited temperature ranges (e.g., 15–50°C) the observed fluorescence intensity for many species is approximately inversely proportional to temperature.
- For different fluorophores the intensity change may lie in the range  $c. (-)1$ –5% per °C. For example, tryptophan has a temperature coefficient of  $\sim -3.5\%$  per °C over the range 20–30°C, while for quinine the coefficient is closer to  $-2\%$  per °C.
- Molecules with apparently similar fluorophores but with different substituents often show markedly different temperature coefficients. Internal flexibility and steric hindrance effects limiting vibrations may be responsible.
- There is no evidence that long-wavelength fluorophores, despite small ground state–excited state energy differences, show large temperature dependence effects.

Maintaining the temperature of the sample cuvette with variations of not more than  $\pm 0.1^\circ\text{C}$  should ensure that temperature effects are negligible compared with other sources of variation. Fluorescence polarization values are particularly susceptible to temperature effects and control at the level of  $\pm 0.05^\circ\text{C}$  or better may be desirable.

## Fluorescence Quantum Yields

Equations [4]–[7] include the term  $\phi_f$ , the quantum yield of fluorescence, and it is evident that, other factors being equal, fluorophores with high quantum yields will provide more sensitive analyses. Moreover, quantum yield values provide important information on electronic transitions in molecules. In practice, however, absolute quantum yield measurements are quite difficult to make, for a variety of technical reasons. Several approaches have been used. The most direct approach involves comparing the intensity of light emitted from a fluorescent solution in a cuvette with that from an ideal scattering solution, such as a colloidal matrix. Such a scatterer can be assumed to scatter all photons incident on it, i.e., to have an effective quantum yield of 1. This method is complicated by the strong polarization of scattered light, and the sensitivity of the detection components in a spectrometer to this phenomenon. A second approach is a calorimetric one, i.e., the energy *not* emitted by the sample as light is measured, for example, by photoacoustic techniques. This method gives results in good agreement with purely optical approaches, but has not been applied frequently as specialized equipment is required. The method most commonly used is a secondary one, in which the fluorophore under study is compared with a standard material of known quantum yield. If the two samples, studied in the same instrumental conditions, have integrated fluorescence intensities (i.e., areas under their corrected fluorescence spectra) of  $S_1$  and  $S_2$ , absorbances at their own excitation wavelengths of  $A_1$  and  $A_2$ , and quantum yields  $\phi_1$  and  $\phi_2$ , then:

$$\frac{S_2}{S_1} = \frac{A_2}{A_1} \frac{\phi_2}{\phi_1} \quad [10]$$

Unhappily, relatively little agreement has been reached on a range of fluorophores covering a range of wavelengths, which can be used as standards. One manufacturer (Molecular Probes<sup>®</sup>) sells a set of reference solutions (quinine in 0.1 mol l<sup>-1</sup> sulfuric acid, fluorescein in 0.1 mol l<sup>-1</sup> aqueous NaOH, 5-carboxytetramethylrhodamine in methanol, sulforhodamine 101 in ethanol, and Nile Blue in ethanol),

which cover the excitation wavelengths  $\sim 350$ – $650$  nm, and emission wavelengths  $\sim 450$ – $670$  nm. The first two of these materials are assigned standard quantum yields of 0.55 and 0.92, respectively. These values would be accepted by most workers in the fluorescence community and can be used to estimate other quantum yields. However, many quantum yield values reported in the literature are of rather doubtful accuracy.

### Introduction

The usefulness of fluorescence spectroscopy for clinical and drug analysis is beyond doubt. In fact, judging by the number of analyses done per day, the most extensive use of this technique is probably in clinical and pharmaceutical analysis. A large number of substances of biomedical interest possess intrinsic fluorescence at either room temperature or low temperatures, which has been widely exploited for performing basic studies and developing a host of analytical methods. Also, many therapeutic and abuse drugs exhibit native fluorescence in organic and neutral solutions or even in strong acids and bases, which has been used for analytical purposes.

Nonfluorescent or weakly fluorescent analytes can be modified to obtain fluorescent products. The changes involved in the process can be of a chemical or physicochemical nature. The former, usually in the form of derivatization reactions, include chemical treatments using redox, complex formation, and substitution reactions or incorporation of a fluorophore through a chemical (e.g., condensation) reaction. Physicochemical modification of a nonfluorescent or weakly fluorescent substance can be accomplished in a number of ways including changes in the molecular environment arising from a solvent changeover, addition of a chemical compound such as a surfactant or cyclodextrin to protect fluorophores from their molecular environment, and energy

transfer processes between fluorescent and nonfluorescent molecules.

A systematic description of the scope of fluorescence spectroscopy in clinical and drug analysis is rendered difficult by the very large number of determinations reported so far. For reasons of space, this article can only present an overview of the wide variety of applications of this technique in these analytical fields, such as chromatographic and electrophoretic methods, its use in enzymatic and immunochemical assays and in biosensors, and its usefulness in new research areas such as proteomic studies.

### Selectivity and Sensitivity of Fluorescence Spectroscopy in Clinical and Drug Analysis

Direct fluorescence measurements in biological samples are hindered by several factors including concentration effects, background effects arising from Rayleigh or Raman scattering, solvent effects (e.g., interfering nonspecific fluorescence and quenching), and sample matrix effects. Thus, a serum or urine sample may contain a variety of fluorescing substances, such as proteins and bilirubin, that are a potential source of unwanted background fluorescence. Light scattering by proteins and lipoproteins can also contribute to this negative effect. Selectivity is also a major problem in the determination of drugs in their dosage forms, which are often multicomponent preparations. The lack of selectivity in fluorescence analysis of clinical and pharmaceutical samples usually calls for a prior sample cleanup step using a separation technique,

### Introduction

The usefulness of fluorescence spectroscopy for clinical and drug analysis is beyond doubt. In fact, judging by the number of analyses done per day, the most extensive use of this technique is probably in clinical and pharmaceutical analysis. A large number of substances of biomedical interest possess intrinsic fluorescence at either room temperature or low temperatures, which has been widely exploited for performing basic studies and developing a host of analytical methods. Also, many therapeutic and abuse drugs exhibit native fluorescence in organic and neutral solutions or even in strong acids and bases, which has been used for analytical purposes.

Nonfluorescent or weakly fluorescent analytes can be modified to obtain fluorescent products. The changes involved in the process can be of a chemical or physicochemical nature. The former, usually in the form of derivatization reactions, include chemical treatments using redox, complex formation, and substitution reactions or incorporation of a fluorophore through a chemical (e.g., condensation) reaction. Physicochemical modification of a nonfluorescent or weakly fluorescent substance can be accomplished in a number of ways including changes in the molecular environment arising from a solvent changeover, addition of a chemical compound such as a surfactant or cyclodextrin to protect fluorophores from their molecular environment, and energy

transfer processes between fluorescent and nonfluorescent molecules.

A systematic description of the scope of fluorescence spectroscopy in clinical and drug analysis is rendered difficult by the very large number of determinations reported so far. For reasons of space, this article can only present an overview of the wide variety of applications of this technique in these analytical fields, such as chromatographic and electrophoretic methods, its use in enzymatic and immunochemical assays and in biosensors, and its usefulness in new research areas such as proteomic studies.

### Selectivity and Sensitivity of Fluorescence Spectroscopy in Clinical and Drug Analysis

Direct fluorescence measurements in biological samples are hindered by several factors including concentration effects, background effects arising from Rayleigh or Raman scattering, solvent effects (e.g., interfering nonspecific fluorescence and quenching), and sample matrix effects. Thus, a serum or urine sample may contain a variety of fluorescing substances, such as proteins and bilirubin, that are a potential source of unwanted background fluorescence. Light scattering by proteins and lipoproteins can also contribute to this negative effect. Selectivity is also a major problem in the determination of drugs in their dosage forms, which are often multicomponent preparations. The lack of selectivity in fluorescence analysis of clinical and pharmaceutical samples usually calls for a prior sample cleanup step using a separation technique,

such as liquid-liquid or solid-phase extraction. Dialysis is used in some cases to deproteinize serum. As regards sensitivity, the facts that many drugs are administered in very low doses and that biological fluids usually contain a large number of substances at low concentrations call for highly sensitive procedures.

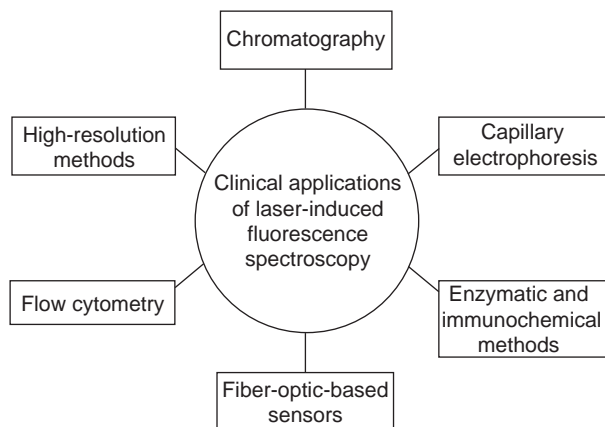

The selectivity and sensitivity of fluorimetric analysis can be enhanced by use of a number of alternatives to conventional fluorimetry. The usefulness of long-wavelength fluorophores in avoiding the interference of the sample matrix has been shown in numerous applications. Advances in fluorescence instrumentation allow interferences to be minimized or even eliminated altogether, thereby providing higher resolutions. Stray and scattered light can now be avoided. Also, sample preparation and handling techniques have been improved in parallel, and a number of enhanced spectral calibration and correction procedures have been developed. In addition, computerized fluorimetric instrumentation endows assays with higher precision and obviates the need for interpretation of vast amounts of data.

The determination of extremely low concentrations call for laser-induced fluorescence (LIF) spectroscopy, which is hardly affected by stray light thanks to the high monochromaticity of the beams used. Although laser instruments are still far from commonplace in the clinical laboratory, they have been used in a number of interesting applications (Figure 1) such as chromatographic and electrophoretic methods since the good collimation of the laser beam allows its full intensity to be focused onto a very small area. Also, the detection limits of laser-based enzymatic and immunochemical methods are typically lower than those afforded by conventional radiation sources. Other interesting applications of LIF in biomedical analysis involve the use of

fiber-optic sensors, which enable *in vivo* measurements, and the application of fluorescence line-narrowing spectrometry, a low-temperature solid-state spectroscopy, to a variety of biomolecular studies including cellular macromolecular damage and chemical carcinogenesis. Lasers are also very useful in fluorescence microscopy and flow cytometry.

Fluorescence spectroscopy has been used in a number of classical diagnostic tests, the capabilities of many of which have been enhanced by exploiting the advantages offered by the development of fluorimetric instrumentation. Thus, screening of newborns with normal tyrosine levels for phenylketonuria and hyperphenylalaninemia is routinely carried out using fluorimetric assays. Fluorimetric procedures for noradrenaline, adrenaline, dopa, dopamine, and their metabolites allow the specific type of catecholamine and its concentration to be determined, which in turn permits characterization of pheochromocytomas and neuroblastomas. Many vitamins and their metabolites are best quantified for diagnosis of avitaminosis by fluorimetric assay. The mineral metabolism of calcium and magnesium has been studied fluorimetrically in many laboratories. Fluorimetric assays for porphyrins are very simple and sensitive. Adrenocortical function is usually assessed by using a fluorimetric procedure for corticosteroids. Also, urinary estrogens are typically assayed fluorimetrically in clinical laboratories.

Although fluorescence spectroscopy is usually applied in solution, fluorescence measurements on solid surfaces are becoming a major choice for screening of drugs of abuse, pharmaceuticals, and clinical substances. In addition to thin-layer chromatographic plates, other solid-surface attachments such as electrophoresis steps, silicone rubber pads, and sodium acetate layers can be used for this purpose. Also, a number of fluorimetric methods use immobilized enzymes or immunoreagents. In this particular analytical field, measurements can be made on specially designed fluorimetric pads containing all the reagents required for quantitative assay, with substantial time savings.

**Figure 1** Scope of application of LIF spectroscopy in clinical analysis.

## Chromatographic and Electrophoretic Methods

Fluorescence spectroscopy has reached a prominent position among the detection systems used in conjunction with separation techniques, mainly liquid chromatography (LC) and capillary electrophoresis (CE). The literature abounds with references to clinical and pharmaceutical applications of LC with fluorimetric detection. Thus, as can be seen in

Table 1, a host of methods for the determination of therapeutic and abuse drugs using LC and native fluorescence measurements have been described. There are also numerous methods for drug determination in clinical samples involving pre- or postcolumn derivatization reactions (Table 2). Fluorescence labeling through covalent binding is the type of reaction most commonly used in this context. Postcolumn photochemical reactions induced by ultraviolet irradiation are other useful means for converting some substances such as phenothiazines into strongly fluorescent products. Another possibility

is to exploit the dependence of the emitted radiation intensity on the particular environment of a fluorescent compound, which is added to the eluent. Thus, lipids have been determined by mixing a continuous stream of aqueous solution containing a fluorescent dye with the column effluent, which results in a certain level of baseline fluorescence that is increased by the presence of lipids, probably because of the enhancing effect of the micelles formed by the lipids.

LC with fluorimetric detection is also suitable for therapeutic drug monitoring (TDM) purposes. For

instance, it has been applied to the determination of selective serotonin reuptake inhibitors, which are used as antidepressants. Table 3 shows some features of these methods, which involve a sample pretreatment

by liquid-liquid or solid-phase extraction. An interesting application of LC with fluorimetric detection to drug analysis is the separation of enantiomers. For instance, cardiovascular agents

represent one of the largest prescribed class of pharmaceuticals since cardiovascular diseases are one of the main causes of mortality in the world. Many of these compounds are still administered as a racemic mixture, although (R)- and (S)-individual enantiomers usually possess different pharmacological and toxicological activities. Table 4 shows some examples of the usefulness of fluorimetry in this area.

Probably the main analytical application of CE is, for the present, the determination of drug substances and, indeed, the penetration of this technique into the pharmaceutical industry, after a slow start, is now a reality. Also, CE is becoming a tool complementary to established LC methods for drug determination in biological samples. The separation efficiency of CE can be greater than that of LC, and CE can be less expensive because organic solvent consumption is lower and the capillaries are cheaper. However, CE cannot yet be regarded as a routine technique in clinical and drug analysis. There are still several problems such as the lack of sensitivity and the need for sample pretreatment to remove interfering species and particulate matter that can easily clog the CE system. Sometimes CE is not sensitive enough to determine low concentrations because of the small sample injection volume, which is typically only a few nanoliters and the short optical path length for on-capillary detection.

Fluorescence detection in CE is generally performed using laser sources for excitation instead of conventional lamps, with the aim of concentrating enough radiation energy inside the capillary. However, although the use of LIF provides extremely high sensitivity, it is only applicable for some analytes as lasers are commercially available only with a limited number of wavelengths. For instance, some drugs like anthracyclines fluoresce when excited at 488 nm, which is the typical emission wavelength of the argon ion laser. Thus, detection limits of 0.5 and 2 ng ml<sup>-1</sup> have been obtained for idarubicin and doxorubicin,

respectively, using a sample volume of 0.1 nl plasma with a commercial CE instrument equipped with an argon laser. The use of a He–Cd laser emitting at 325 nm has allowed also the determination of several drugs, such as ciprofloxacin, methotrexate, and zolpiden, in biological fluids using CE–LIF. An alternative to direct fluorescence detection is the use of a derivatization reaction, although it can involve a loss of selectivity. In spite of these limitations, the use of LIF detection is one of the preferred options for improving sensitivity in the analysis of biological samples using CE. The interest in the near-infrared region in CE using diode lasers and long-wavelength fluorophores has grown in the last years as it is a useful option for avoiding background interferences. This approach has been applied to the determination of amino acids, peptides and proteins, and DNA sequencing and fragment analysis.

The usefulness of LIF in DNA analysis has been demonstrated using fluorescent dyes as labels in CE and denaturing LC (DHPLC) techniques. It has been suggested that CE is preferable for DNA sizing and sequencing analyses and DHPLC is effective for screening of genetic mutations and polymorphisms.

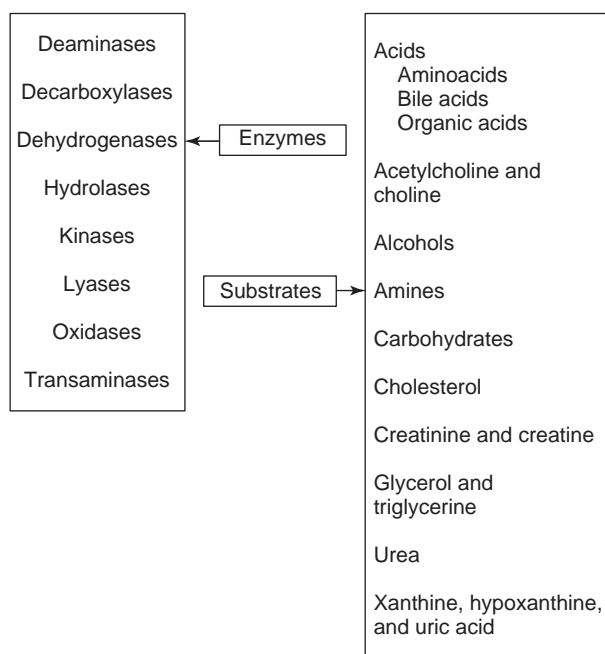

## Enzymatic Assays

The high sensitivity of fluorescence spectroscopy and the selectivity of enzymatic assays are responsible for the increasing use of fluorimetric methods in enzymology. Enzyme determinations usually involve the use of kinetic methodology for measuring the rate of formation of the fluorescent product, while both equilibrium and kinetic methods are used to determine the substrates. Fluorimetric measurements on enzyme-catalyzed reactions have been used for a long time to determine a variety of enzymes and substrates (Figure 2).

NADH and NADPH, the respective reduced forms of NAD<sup>+</sup> and NADP<sup>+</sup>, are highly fluorescent; hence, all NAD<sup>+</sup>- and NADP<sup>+</sup>-dependent reactions involved in enzymatic assays can be monitored fluorimetrically with a sensitivity higher than those of absorptiometric techniques by two or three orders of magnitude. Reactants must be used at much lower concentrations, and detection limits of 10<sup>-9</sup> mol l<sup>-1</sup> or even lower can be achieved. Numerous methods for enzyme determination involve the use of substrates that are transformed into highly fluorescent products. For instance, *p*-hydroxyphenylacetic acid has been used widely as a substrate for the determination of several oxidases such as glucose oxidase and xanthine oxidase.

**Table 4** Chromatographic enantioseparation of cardiovascular drugs using fluorescence detection

Analyte	Sample
Sotalol	Plasma, urine
Propranolol	Urine

Albuterol	Serum
Verapamil and norverapamil	Plasma
Gallopamil	Plasma
Mexiletine	Serum
Ibutilide	Plasma
Artilede	Plasma

**Figure 2** Fluorimetric determinations based on enzyme-catalyzed reactions.

Enzymatic substrates yielding fluorescent products that emit at long wavelengths are a useful alternative for avoiding background signals. Thus, naphtho-fluorescein diphosphate has been proposed as a substrate for alkaline phosphatase, which hydrolyses the substrate yielding fluorescent naphthofluorescein. This system has been used for the determination of theophylline at therapeutic levels based on the inhibitory effect of this drug on the enzyme activity. Fluorogenic substrates for proteases containing Cresyl Violet have been synthesized to visualize protease activity in single cells. Also, a tetra-substituted amino aluminum phthalocyanine has been described as a red-region substrate for peroxidase. The system has been applied to the determination of glucose in serum by coupling a glucose oxidase-catalyzed reaction.

## Fluoroimmunoassays

Immunochemical methods are routinely used in the clinical laboratory on account of their special features, particularly their high selectivity and the commercial availability of automatic instrumentation for their implementation. Since the earliest immunoassay involving radioisotopes was reported, a large variety of alternative immunoassays have been developed to circumvent the shortcomings of radioimmunoassay, many of them using fluorescence detection. Some fluoroimmunoassays (FIAs) developed with this purpose, such as fluorescence-quenching

**Table 5** Scope of application of FPIA in clinical analysis

<i>Therapeutic drugs</i>	<i>Illicit drugs</i>	<i>Hormones</i>
Antibiotics	Amphetamines	Thyroid agents

Antiasthmatics	Benzodiazepines	
Cardiac glycosides	Opiates	
Antineoplastics		
Tricyclic antidepressants		

and fluorescence-enhancing immunoassays, are scarcely sensitive enough or applicable, which hinders their use by clinical laboratories. However, there are some FIAs widely used at present using automated instrumentation.

Fluorescence polarization spectroscopy is applied in homogeneous immunoassay for the determination of small molecules such as hormones and therapeutic and abuse drugs (Table 5). It is routinely used in TDM to quantify drug levels in plasma and serum specimens. The most serious problem faced in applying fluorescence polarization immunoassay (FPIA) to serum samples is its relatively poor sensitivity, which is limited by three factors: (1) the background fluorescence of serum samples, which arises partly from scattered light and partly from the intrinsic fluorescence due to the presence of fluorescent compounds such as NADH and bilirubin; (2) nonspecific binding of the tracer to serum proteins such as albumin, which is probably the chief agent responsible for this interaction because of its versatile ligand properties and affinity for many anionic dyes (e.g., fluorescein, the most commonly used label in FPIA); and (3) the presence of polarizers in the excitation and emission beams, which reduces the light intensity and potential sensitivity by a factor of up to ~10. In spite of these shortcomings, the advent of microprocessor technology, improvements in optics and detectors, and advances in tracer design and immunological techniques have turned FPIA into a practical technique for use in the clinical laboratory.

Fluorescence energy transfer immunoassay is another homogeneous format based on a nonradiative fluorescence resonance energy process. One of the immunoreagents is labeled with a donor fluorophore, while another immunoreagent is labeled with an acceptor chromophore, which may or may not be fluorescent. There should be considerable overlap between the emission spectrum of the donor and the absorption spectrum of the acceptor. The formation of the antigen-antibody complex gives rise to the quenching of fluorescence of the donor, while the fluorescence of the acceptor increases if the acceptor is fluorescent. Besides fluorescence intensity changes,

the energy transfer process also induces fluorescence lifetime changes, which can be measured by using pulsed or modulated excitation sources. Because the fluorescence properties of the unbound species essentially remain unchanged, homogeneous formats are possible.

Among homogeneous fluoroimmunoassays based on conventional fluorimetry, substrate-labeled fluoroimmunoassay is another alternative for both hapten and protein determination using a fluorescent label. As in other homogeneous competitive immunoassays, the sensitivity is limited by the serum background fluorescence and the limited amount of tracer that can be used.

The combined use of time-resolved fluorescence spectroscopy and lanthanide (particularly europium(III)) chelates as labels has given rise to time-resolved fluoroimmunoassay (TRFIA). It provides a high sensitivity as a result of several assets of europium chelates, such as their large Stokes shifts, which make separation of the excitation and emission wavelengths very easy; their narrow emission bandwidths, which allow the use of narrow bandpass emission filters with no loss of energy; and the long life of the fluorescence they emit, such that the short-lived (1–20 ns) background fluorescence of serum, solvents, cuvettes, and reagents obtained upon flash excitation of the sample can be allowed to decay so that the only possible fluorescent signal will be due to the europium chelate ( $\sim 500 \mu\text{s}$ ). As a result, interfering background fluorescence, the greatest hurdle for other FIAs, is reduced by two or three orders of magnitude. TRFIA requires the use of a xenon flash lamp or a laser excitation source for obtaining time-resolved measurements. The process is carried out in two steps: the reagent (antigen or antibody) labeled with a nonfluorescent europium chelate is subjected to the immunoreaction, and then the europium is released and bound to another chelating agent, which produces an intense fluorescence arising from an energy transfer process. This requires the use of coated tube technology, in which usually a europium-labeled antibody reacts with the immobilized antibody–antigen complex on the solid phase (i.e., the sandwich technique). TRFIA is the basis for a host of applications, including in gynecology, thyroid disease, cancer diagnosis, viral infections, cytotoxicity, and enzyme activity measurements. Many of these applications are now used in routine clinical analyses implemented with commercially available kits and automated instrumentation.

Another application of lanthanide ions in immunoassay, in this case terbium(III), is enzyme-amplified lanthanide luminescence. This approach involves the use of the substrate of an enzyme that does not form

a fluorescent chelate with terbium(III), but is converted to a product that does form such a chelate. Alkaline phosphatase (ALP) has been used for labeling, and several compounds, such as salicyl phosphate, fluorosalicyl phosphate, and diflunisal phosphate, as substrates. These compounds cannot coordinate efficiently with the terbium(III)–ethylene-diaminetetraacetic acid complex, but the fluorescent ternary complex is formed in the presence of ALP, which splits the phosphate ester and releases the terbium ligand. This approach has been applied in immunoassay to the determination of several species, such as  $\alpha$ -fetoprotein, thyrotropin, and interleukin 6, leading to very low detection limits.

## Fluorosensors

Optical sensors based on fluorescence spectroscopy and immobilized enzymes or immunoreagents (biosensors) are widely used at present because of the high selectivity they provide. The earliest fluorosensor for glucose was developed in 1980 and was used to measure the amount of oxygen consumed during its enzymatic oxidation by glucose oxidase in the presence of catalase, which is covalently immobilized. Since this biosensor was developed, this methodology has been used for the determination of a large number of species of clinical interest. Fluorosensors have also been widely applied to pharmaceutical analysis. Thus, penicillin can be assayed by using a pH fiber sensor onto which penicillinase is immobilized. The enzyme catalyses the hydrolysis of penicillin to penicilloic acid, and the resulting increase in the hydrogen ion concentration is monitored. Oxygen sensors based on the immobilization of ruthenium(II) complexes, which show long-wavelength fluorescence, have been modified into biosensors for the determination of clinical parameters such as glucose or free cholesterol by immobilizing the corresponding enzyme also.

The development of antibody-based biosensors presents more difficulties than enzyme-based biosensors as the antigen–antibody interactions are not readily reversible because of the high values of the affinity constants. Another limitation is that the physicochemical changes resulting from the immunochemical reaction are often insufficient to provide detection limits comparable with those of conventional analysis. As a consequence, indirect systems have been developed that rely on the use of enzyme- or fluorescent-tagged reagents. Both competitive and sandwich formats are used. Evanescent wave-induced fluorescence is frequently chosen to avoid possible interferences from the bulk media. For

instance, an immunosensor based on the use of the dye Cy5, a long-wavelength fluorophore, has been described for the determination of cocaine metabolites in urine using a competitive format.

Fiber-optic sensors involving the use of LIF measurements are of great interest in biomedical analysis as they can be used for measuring analytes remotely, continuously, and directly within the fluid to be analyzed. This technique has been employed in cytological applications for diagnosing tumors and atherosclerosis. The ability to focus intense beams tightly to subcellular dimensions is significant in obtaining measurable signals from weakly fluorescent cells and essential when morphological information is required. There is a growing interest in the miniaturization of the sensors, which allows the reduction of the sample volume and the response time. The analytical properties of fluorescent nanosensors allow accurate analysis of biological systems at the single cell level. To prevent cytotoxicity upon insertion of the sensor into the cell, the sensing reagent must be isolated from the cellular environment by a biocompatible matrix that is selective to the intracellular analyte. The application of these sensors has been greatly assisted by recent advances in digital fluorescence imaging instrumentation.

## Proteomics Studies

Proteomics includes a series of key technologies that are being used to identify proteins and map their interactions in a cellular context. With the sequencing of the human genome, the scope of proteomics has shifted from protein identification and characterization to include protein structure, protein function, and protein-protein interactions. Fluorescence-based and mass spectrometry (MS)-based methodologies offer new capabilities in the field of proteomics through the performance of multiplex quantitative analysis. Two-dimensional gel electrophoresis (2D-GE) is a separation technique used widely in proteomics. Visualization of proteins in gels is accomplished through staining techniques. Several fluorescent stains have proved to be suitable for incorporation into integrated proteomics platforms for global analysis of protein regulation. The linear dynamic range of detection using fluorescent stains is usually superior to colorimetric or reverse stains. Fluorescence measurements in 2D-GE are obtained using charge-coupled cameras or laser-based detectors as image-acquisition devices. For proteomics work, the protein stains must be compatible with MS as the coupling of 2D-GE to MS provides both precise mass determination and protein identification.

## Other Applications

There are other fluorimetric techniques of interest to clinical and pharmaceutical analyses. Thus, the performance of total fluorescence spectrometry in multicomponent and complex analyses has been assessed. The overall fluorescence of human serum and urine can be used as a diagnostic tool in clinical chemistry, particularly in view of its selectivity towards even quite small changes in the location of the peaks and their relative intensities. This is the foundation of pattern recognition methods for detection of pathological deviations from normal status. This technique is also suitable for rapid screening of a variety of drugs since the samples require virtually no treatment.

Derivative and synchronous fluorescence spectrometry, both individually and jointly, have been used in clinical and drug analyses as a means of enhancing selectivity. Thus, derivative synchronous fluorescence spectrometry allows the direct determination of catecholamines and porphyrins in urine and pyridoxal and its derivatives and cephalosporins in serum. In addition to its use in immunoassay, fluorescence polarization spectroscopy has been employed to study macromolecules and to carry out structural investigations of the binding of small molecules to proteins as well as to assess fetal lung maturity. It has also been applied for single nucleotide polymorphisms genotyping and in drug discovery research using targets such as kinases, phosphatases, proteases, G-protein coupled receptors, and nuclear receptors. Fluorescence microscopy for characterizing biological surfaces is increasingly being cited in the analytical literature. For instance, it is routinely used to study the location and movement of intracellular species.

Fluorescence probes are widely used in flow-cytometric applications in the clinical laboratory. Some flow cytometers include argon lasers and enable right-angle fluorescence, right-angle light scatter, and forward light scatter measurements. In this way, the cellular DNA content, one of the most commonly determined parameters, can be measured fluorimetrically using DNA-specific fluorescent dyes. Another interesting application of this approach is the determination of intracellular ionized calcium concentrations. Several strongly fluorescing  $\text{Ca}^{2+}$ -sensitive dyes can be used for single-cell measurements. In multilaser flow cytometers, several fluorescent dyes are used in order to correlate the intracellular  $\text{Ca}^{2+}$  concentration with those of cell surface antigens or some other parameters. A number of immunofluorescence studies based on flow cytometry have been carried out by directly conjugating a fluorophore

(usually fluorescein isothiocyanate) to an antibody (direct immunofluorescence) or a second antibody that reacts with the first (indirect immunofluorescence). This allows one to ascertain the presence of cell surface antigens.

Much work has been carried out in the development of new fluorescent probes suitable for the detection and quantification of biologically significant molecules both *in vivo* and *in vitro*. For instance, aptamers are oligonucleotides that in a particular conformation exhibit molecular recognition. They show affinity for both small molecules and macromolecules. Aptamer beacons are aptamers that incorporate a fluorescence-quenching pair, which is used to indicate a consequent change in conformation upon binding. These compounds are selected for specific binding to a variety of molecular targets, ranging from small organics to proteins. Their usefulness in molecular recognition is being studied using affinity chromatography, capillary electrophoresis, and biosensors, although there are still relatively few examples of the use of aptamer beacons in analysis, which can be explained by their relatively recent development.

### Introduction

Environmental analyses often involve the determination of low concentrations (viz., a few nanograms or picograms per milliliter) that require the sensitivity of fluorescence analysis. Most environmental applications of fluorimetric methods involving air, water, or soil pollution are concerned with polycyclic aromatic compounds, which feature high fluorescence quantum yields. However, in recent years, the scope of fluorimetric techniques has been successfully extended to other major nonfluorescent pollutants such as isocyanates after conversion into fluorescent species. But fluorescence detection and determination of pollutants is still confronted with problems arising from a lack of selectivity. Such problems are currently

being addressed using a number of approaches, mainly involving the use of separation techniques (liquid chromatography, LC, or capillary electrophoresis, CE), multiparametric information (e.g., spectral change, intensity, lifetime, polarization, etc., of fluorescence), low-temperature fluorimetry, and immunoanalytical techniques. These approaches are not incompatible, so two or three are often used in combination. Their main applications to the determination of pollutants are briefly discussed in this article.

### LC-Fluorescence Detection

#### Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) occur widely in the environment and, even though they come from both natural (volcanic eruptions and forest and prairies fires) and anthropogenic (combustion of fossil fuels, waste incineration, coke and asphalt

production oil refining, etc.) sources, human pollution contributes the larger proportion by far. Due to their environmental concern, PAHs are included in the US EPA and in the European Union priority lists of pollutants. US EPA has identified 16 unsubstituted PAHs as priority pollutants, some of which possess carcinogenic and mutagenic activities. The European list contains six target PAHs.

A number of analytical techniques have been used for the determination of PAHs in complex environmental samples. Gas chromatography with either flame ionization or mass spectrometry detection and LC with ultraviolet (UV) or fluorimetric detection are the techniques most widely used. Fluorescence spectroscopic detection provides both a sensitive and, often more important, a selective means for monitoring PAHs in liquid chromatographic effluents. PAHs make a virtually ideal class of fluorophores. In fact, PAHs possess large molar absorptivities (usually greater than  $10^4 \text{ mol}^{-1} \text{ cm}^{-1}$ ) and exhibit maximum absorption in the near-UV or visible region, in addition to high fluorescence quantum yields (normally above 0.2 and often approaching 1.0) and long fluorescence lifetimes (a few tens to hundreds of nanoseconds). The extremely high sensitivity in fluorescence emission has lowered the minimum detectable concentration of most PAHs to near sub-picogram levels (detection limits as calculated from the signal-to-noise ratios for the individual peaks in the chromatograms). An additional feature is that the fluorescence intensity of PAHs is linearly dependent on their concentration over ranges of as many as six orders of magnitude.

Reversed-phase LC on chemically bonded  $\text{C}_{18}$  (octadecylsilane) stationary phases is by far the most popular liquid chromatographic mode for separation of PAH compounds. Resolution is greatly influenced by the type of synthesis used to prepare the bonded phase. Good resolution can be achieved for the 16 US EPA PAHs on polymeric  $\text{C}_{18}$  phases. However, some isomers are unresolved (chrysene and benzo[*a*]anthracene) or only partially resolved (benzo[*ghi*]perylene and indeno[1,2,3-*cd*]pyrene, benzo[*k*]fluoranthene, and benzo[*b*]fluoranthene, or fluoranthene and acenaphthene) when monomeric  $\text{C}_{18}$  phases are used.

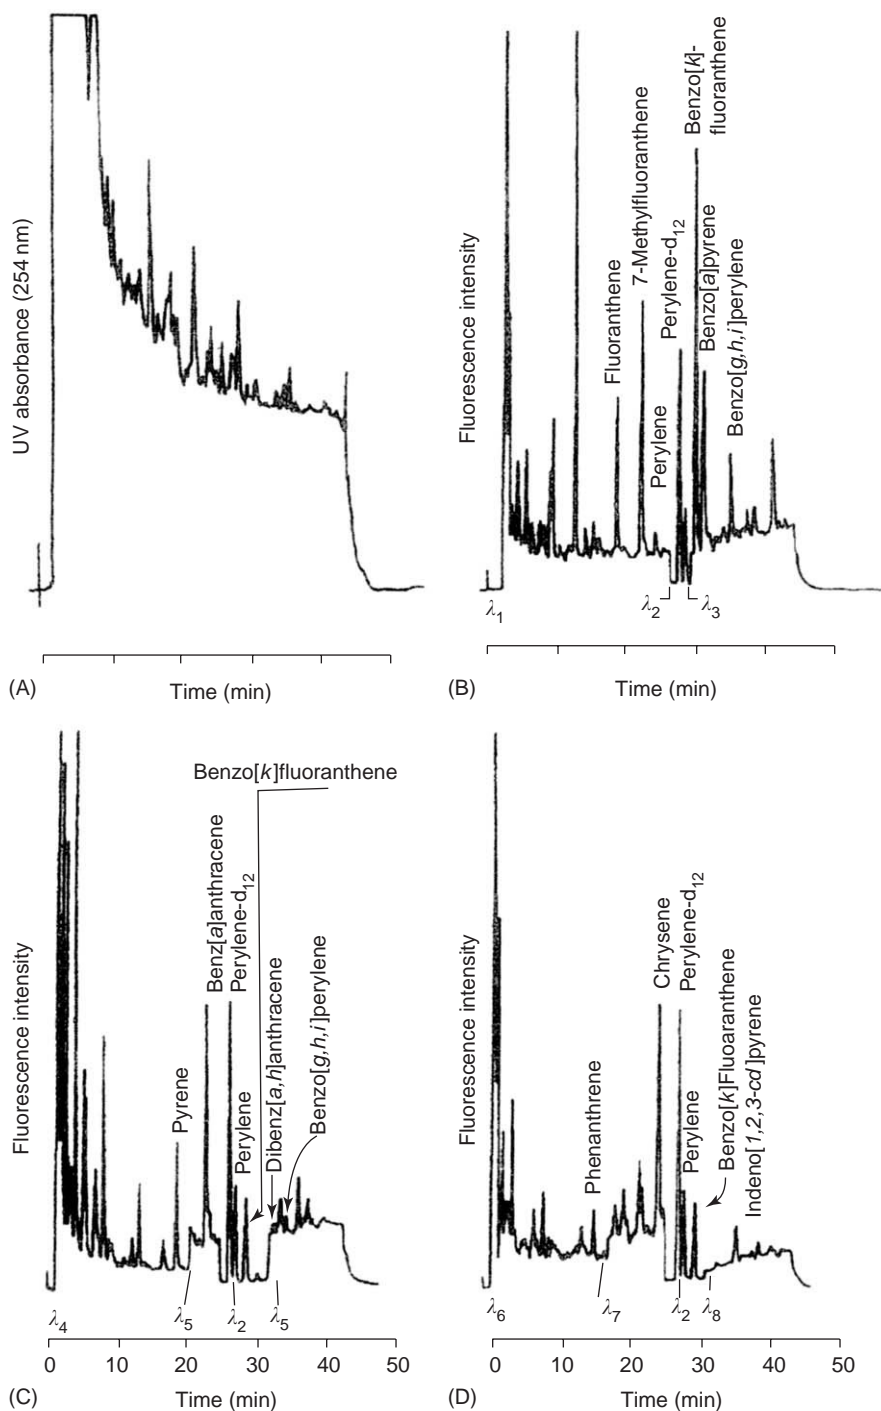

High selectivity is generally obtained for the determination of PAHs in environmental samples using LC-fluorescence detection. Since the retention times obtained using a  $\text{C}_{18}$  LC column and the optimal excitation and emission wavelengths for individual PAHs are known, time programming of the fluorimeter wavelength settings can be used to minimize interference from coeluting compounds. Obviously, the excitation and emission wavelengths to be used

with a given PAH need not be their optimal wavelengths, but instead should be chosen so as to obtain the most selective fluorescence response possible for that PAH in the presence of anticipated coeluting compounds. In this way, the selectivity of fluorescence spectrometry can be used to simplify the separation process. **Figure 1** illustrates results typically obtained using this operational procedure.

Retention in reversed-phase LC increases with the number of aromatic carbons and the extent of alkylations. Therefore, the identification of PAHs based on chromatographic retention is confronted with a serious problem: coelution of alkyl-substituted homologs of smaller PAHs. Thus, some alkylphenanthrenes and alkylanthracenes elute in the region where fluoranthene and pyrene elute; also, alkylpyrenes and alkylfluoranthenes elute in the same region as benzo[*a*]anthracene, chrysene, and triphenylene. This shortcoming has been circumvented in the past by initially fractionating complex PAH mixtures into isomer families on an aminosilane column prior to isolation of individual isomers on a  $\text{C}_{18}$  column in the reversed-phase mode. The resulting chromatograms are free of any interference from alkylated homologs of smaller aromatic carbon numbers.

Quantitation of PAHs requires the use of internal standards with the same number of aromatic carbons as the analytes. Perdeuterated PAHs make excellent internal standards in this respect. Even though the deuterated and nondeuterated analogs of a given PAH are virtually indistinguishable by solution fluorimetric, the  $\text{C}_{18}$  column can isolate deuterated and nondeuterated PAHs with sufficiently high resolution for the fluorescence of each compound to be measured with no appreciable interference from the other. Probably the most suitable internal standards for each isomer family are the perdeuterated analogs of the isomers that elute first, since perdeuterated PAHs would then yield the first elution peak in the reversed-phase liquid chromatogram, thereby minimizing the risk of coelution with alkyl-substituted PAHs within a given isomer group. Thus, the ideal internal standards for analysis of isomer families would be perdeuterated phenanthrene (14 aromatic carbons, ACs), fluoranthene (16 ACs), triphenylene (18 ACs), benzo[*i*]fluoranthene (20 ACs), and benzo[*ghi*]perylene (22 ACs).

The combined use of LC and fluorescence detection for the determination of PAHs has some disadvantages, foremost among which is the long sequence of steps involved and the overall time required to complete analyses. By the same token, the hazards of loss of sample components (e.g.,

**Figure 1** Comparison of UV absorption (A) and fluorescence detection (B–D) in the reversed-phase liquid chromatographic separation of PAHs extracted from an urban particulate sample. The different wavelengths in the fluorescence chromatograms were optimal for excitation of the indicated PAH. The chromatograms were acquired by a computer-controlled fluorescence detector, enabling rapid changes in the excitation and emission wavelengths. (Reprinted with permission from May WE and Wise SA (1984) Liquid chromatographic determination of polycyclic aromatic hydrocarbons in air particulate extracts. *Analytical Chemistry* 56: 225–232; © American Chemical Society.)

through volatilization or photodecomposition) or contamination of samples with traces of fluorescent impurities are manifold unless considerable care is exercised.

Other fluorescence systems, in addition to that of variable-wavelength fluorescence detection, are used combined with LC for increasing sensitivity and selectivity. Thus, by using laser-induced

time-resolved fluorimetry, the detection capability for PAHs is improved by one or two orders of magnitude (e.g., the detection limit for benzo[*a*]pyrene is 180 fg). Fluorescence line-narrowing spectroscopy (FLNS) has been also interfaced to LC for online characterization of PAHs. In addition to the high spectral resolution afforded by FLNS, analyzing the separated components at 4.2 K minimizes photo-degradation from the excitation source and provides indefinite detection times for signal averaging. With femtomole detection limits, LC-FLNS can be used for analysis of complex mixtures.

### Isocyanates

Isocyanates, both in monomeric and in polymeric forms, are extensively used for manufacturing polyurethane foams, paints, adhesives, and a number of other products. The health hazards posed by the presence of isocyanates at workplaces, chiefly respiratory tract diseases, have become a source of major concern for occupational health officials. Atmospheric pollution by isocyanates has so far been assessed using two different approaches. One, widely employed to date, involves the determination of several specific isocyanates compounds for which threshold values have been established; the other has become a priority choice for air monitoring programs in recent years and entails determining the concentration of all isocyanate species present.

In determining specific isocyanates by LC one should take into account a few practical considerations. Thus, the extreme reactivity of the -NCO group precludes collection of isocyanates from air without immediate derivatization in order to avoid unwanted reactions of the analytes collected. For this reason, isocyanates are collected in an appropriate derivatization solution held in a bubbler or impinger. The derivatizing reagents used are dissolved in a high-boiling solvent such as toluene in order to avoid excessive volatilization during sampling, after which an aliquot of the absorbing solution is evaporated to dryness and the residue is collected in a solvent compatible with the mobile phase to be used in the liquid chromatographic analysis.

The fluorescent derivatizing reagents most commonly used in this context are primary or secondary amines that react with isocyanates to form ureas according to the reaction given below:

1-Naphthalenemethylamine (NMA), *N*-methyl-1-naphthalenemethylamine (MNMA), and 9-(*N*-methylamino-methyl)anthracene (MAMA) are the three fluorophores most frequently used for this purpose.

The sensitivity of these methods is more than adequate to meet the required detection limits for isocyanates. Thus, the detection limits for hexamethylene-1,6-diisocyanate (HDI) are quoted to be 0.5, 1, and  $0.2 \mu\text{g m}^{-3}$  when using NMA, MNMA, and MAMA, respectively. However, these methods have some major drawbacks. The NMA method results in the appearance of double peaks in the chromatogram for isocyanates for reasons that are still unclear. Also, some NMA derivatives are difficult to dissolve in ordinary liquid chromatographic solvents. On the other hand, MNMA is relatively unstable, so stock solutions of this reagent must be stored refrigerated and prepared freshly every month. The same is the case with MAMA, solutions of which must be freshly prepared from its hydrochloride.

LC methods using fluorescence detection, like most reported LC methods for the determination of isocyanates, have mainly been applied to monomer diisocyanates. In as much as they provide a different detector response for each isocyanate derivative, they require individual isocyanate standards for quantification. As a result, their application to polymeric forms is subject to some drawbacks shared by determinations of polymers using chromatographic procedures, viz., the lack of appropriate standard materials. In fact, such important data as purity, the precise identity of the polymeric components, and the nature of the additives used in the isocyanate polymers available for calibration are often lacking.

Evaluation of airborne polymeric isocyanates has become a major task as hygiene standards are increasingly frequently being defined in terms of total isocyanate concentrations (monomers and polymers) in air. Given the formidable analytical difficulties involved in identifying and quantifying each individual component present in an isocyanate mixture, hygiene standards tend to be based on total (-NCO) ( $\mu\text{g m}^{-3}$ ) data. As a result, isocyanate research in recent years has chiefly been aimed at finding reagents capable of providing a detector response that is proportional only to the amount of isocyanate function (-NCO) being derivatized, irrespective of the type of moiety attached to the -NCO group. In this way, quantification of various isocyanates can be made by use of a single standard for comparison and integration of the individual peak areas after LC separation of the constituent compounds. Tryptamine (3-(2-aminomethyl)indole) has become a standard reagent for this application. This reagent undergoes fluorescence and amperometric oxidation from the conjugate  $\pi$  system of the indolyl moiety, which is located two carbon atoms away from the derivatizing site of the amino group, so the electronic structure of the  $\pi$  system is not perturbed

whatever the types of isocyanates being derivatized. As a result, responses from both fluorimetric and amperometric detectors depend only on the amount of reacted tryptamine, which is stoichiometrically proportional to that of the isocyanate group. The net amount of isocyanate ( $w_{\text{NCO}}$ ) can be readily calculated from

$$w_{\text{NCO}} = \frac{w_{\text{Tryp}}}{160} \times 42$$

where  $w_{\text{Tryp}}$  is the amount of reacted tryptamine, and the divisor 160 and multiplier 42 are the relative molecular masses of tryptamine and isocyanate, respectively.

Although tryptamine derivatives of isocyanates are both fluorimetrically and amperometrically active, fluorescence detection is preferred because of the higher stability and selectivity of the fluorimetric detector. All isocyanates except HDI can be detected at concentrations as low as  $0.5 \text{ ng ml}^{-1}$  in 120 l air samples.

### Pesticides

The use of fluorimetry for the determination of pesticides has been limited by the fact that relatively few of these compounds are strongly fluorescent and by the lack of selectivity of the technique for pesticide screening. In combination with LC (normal, reversed, and ionic phases), direct fluorimetric detection is used for the determination of pesticides exhibiting intrinsic fluorescence strong enough to be analytically useful (e.g., anticoagulant rodenticides such as indanediones and coumarins, carbamates insecticides such as aminocarb, bendiocarb, benomyl, carbaryl, and carbofuran, and some organophosphorus insecticides, including coumaphos and pirimiphos-methyl). Detection limits between 2 and  $20 \text{ ng ml}^{-1}$  are generally obtained.

Online postcolumn derivatization for LC-fluorimetric analysis of nonfluorescent or weakly fluorescent pesticides has mainly involved fluorogenic labeling of *N*-methyl carbamates and metabolites. The labeling reaction is a two-step process consisting of alkaline hydrolysis and posterior reaction of the hydrolysis product with *o*-phthalaldehyde and 2-mercaptoethanol to yield the highly fluorescent 1-hydroxyethylthio-2-methylisindole (EPA method 531.1). The detection limits for surface waters are between 20 and  $30 \text{ ng l}^{-1}$ .

### CE-Laser-Induced Fluorescence Detection

The applicability of CE in environmental analysis is usually rather limited because of poor concentration detection limits in CE compared with LC; however,

combination of CE with laser-induced fluorescence (LIF) detection has dramatically improved the limits of detection for fluorophores. CE-LIF detection of native fluorescence pollutants has focused on the determination of aromatic sulfonates such as naphthalene sulfonates and their amino and hydroxyl derivatives. The technique provides information about their structure, determining them at submicrogram per liter levels, and has been proved to be adequate for real-world environmental monitoring. The emission characteristics of the derivatives are strongly influenced by the nature and the position of the substituents.

On the other hand, derivatization procedures intended to employ LIF detection of nonfluorescent pollutants are numerous. Thus, various schemes for pesticide derivatization have been successfully used in order to determine carbamates (e.g., on-capillary derivatization with quaternary ammonium surfactants that catalyze their thermal decomposition to yield methylamine and use of a separation buffer containing *o*-phthalaldehyde/2-mercaptoethanol) and phenoxy acid herbicides, pyrethroid insecticides, or anilines (e.g., using precolumn derivatization with different fluorescent tags).

### LIF Spectroscopy for Onsite Measurements

The development of portable analytical instrumentation for onsite analysis of contaminants in soil and groundwater has grown significantly over the last decade. In this context, the combination of LIF using fiber optics with cone penetrometer test (LIF-CPT) systems has proven to reduce the costs and increase the efficiency to delineate contamination plumes involving fuels and other petroleum products.

Cone penetrometer testing is an effective means to deliver *in situ* subsurface sensor probes. It is based on driving into subsurface environment a conical steel tip under hydraulic pressure at a nearly constant rate. The tip is advanced by sequentially attaching a series of cylindrical steel extensions or 'push rods' to the assembly that are linked to one another by threadings. The thick-walled CPT push rods are hollow so that they can accommodate the optical fiber bundles.

The basic elements of a LIF-CPT system consist of a laser source, silica-clad silica optical fibers to conduct laser light to the sample and fluorescence to the detector, a sapphire optical window inserted into a brazed or welded channel in the push rod wall, and a detector.

In a typical LIF measurement, wavelength or excited-state decay time are fixed to produce a fluorescent signal from the sample. Calibration is done by

comparing the overall fluorescence pattern with those generated in the laboratory by using simulated samples. The LIF measurements are relatively nonselective, and the information does not necessarily correspond to common environmental designations of contaminants, such as total petroleum hydrocarbon, which are routinely used in soil characterization. Selectivity can be enhanced using multidimensional fluorescence measurements, for example, simultaneous excitation and emission wavelength, decay time, etc.

To date, three LIF-CPT systems have been developed and have proved their field applicability. The pioneering prototype was developed by Lieberman and co-workers at the Naval Research and Development (NRaD) Center in collaboration with the Army's WES laboratories. Later, GD Gillispie's group at North Dakota State University, sponsored by the US Air Force's Armstrong Laboratory, and JE Kenny's group at Tufts University have introduced novel variations with the aim of improving the performance of LIF.

Lieberman's system uses a pulsed nitrogen laser (output wavelength of 337 nm) and two silica-clad silica optical fibers to conduct laser light to the sample and fluorescence to a linear photodiode array detector. By operating the laser at 20 Hz, a fluorescence spectrum can be gathered in 1 s, providing a depth resolution of less than 5 cm at standard push rates. The data produced are most commonly reported as average fluorescence intensities versus depth, which effectively suppresses one dimension of information, the fluorescence emission wavelength, although all emission spectra are stored and may be retrieved for further analysis. The gated photodiode array permits lifetime data to be acquired by scanning the time delay of laser pulses.

In Gillispie's system an Nd:YAG laser is used to pump a rhodamine 6 G dye laser whose pulsed output (0.1 s) is frequency doubled to produce tunable UV light between 260 and 300 nm. It is capable of measuring decay time on the nanosecond scale with the use of a photomultiplier tube and digital oscilloscope. The system may also be stopped at a desired depth to permit the measurement of fluorescence decay curves at multiple emission wavelengths. The resulting data are arranged into a three-dimensional plot representing the wavelength-time matrix and can assist in the identification of species in the contamination mixture being investigated.

The LIF system developed by Kenny's group permits also three-dimensional fingerprint of the sample although it consists of fluorescence intensities as a function of excitation and emission wavelength rather than decay time and emission wavelength.

For this purpose, the system uses a Raman shifter pumped by the fourth harmonic of an Nd:YAG laser to generate multiple laser beams simultaneously in the UV-visible region of the spectrum. Ten beams are separated by a set of prisms and launched into separate silica-clad silica optical fibers and delivered to the sample. Separate collection fibers deliver the fluorescent signals to specific positions on an imaging spectrographic detector.

In field applications, LIF-CPT measurements are primarily used for screening purposes with the aim of delineating the approximate boundaries of a contamination plume so that permanent wells can be efficiently placed for long-term monitoring. For this purpose, the advantages of using the simplicity of Lieberman's LIF-CPT system are clear, since although single-ring aromatic compounds cannot be excited to fluorescence with the single excitation wavelength used, and two-ring aromatic compounds such as naphthalene only produce weak fluorescence, it would be unusual if a site were contaminated by smaller aromatics but not the less volatile, more refractory multiringed organics, which can be discerned by this probe. Gillispie's and Kenny's LIF-CPT systems can obtain plume delineation with increased information content; however, they require more time and more complex equipment.

## Low-Temperature Fluorescence

### Polycyclic Aromatic Hydrocarbons

The exceptionally sharp, quasilinear spectra provided by PAHs under cryogenic sampling have aroused special interest in low-temperature fluorescence measurements on this type of pollutant. It has become apparent that low-temperature fluorimetry can be used to fingerprint specific compounds present at very low levels in PAH mixtures in various environmental matrices (e.g., sediments and biota) without the need for extensive prior cleanup. Low-temperature fluorimetric methods used for the analysis of PAH mixtures rely largely on the Shpol'skii effect (in the frozen-solution or matrix-isolation mode).

The selectivity of the Shpol'skii effect lies in the inherently sharp absorption bandwidths of PAHs (FWHM  $\sim 1\text{--}10\text{ cm}^{-1}$ ) in appropriate frozen *n*-alkane hosts. Techniques based on this effect are usually very sensitive; provided an optimal photomultiplier tube is used, the detection limit for pyrene in a mixture of 10 PAHs in *n*-octane can be made as low as  $5 \times 10^{-10}\text{ mol l}^{-1}$  using an ordinary excitation lamp. The detection limit for benzo[*a*]pyrene is even lower by one order of magnitude; two orders

if laser excitation is employed, which means 20 amol in a 4  $\mu$ l sample volume. Such a high sensitivity is especially significant when samples are available in very small amounts or preconcentration methods are suspected to result in contamination. Shpol'skii fluorimetry in the frozen solution mode has been used successfully to distinguish isomeric alkylated PAHs in various environmental matrices with no prior separation. Thus, it has been applied to the characterization of the alkylated PAH content of diverse marine sediments of geochemical interest: the determination of the concentration ratio of various mono- and dimethylphenanthrenes or of total methylphenanthrenes to phenanthrene itself is a good measure of the maturity of organic matter in sediments.

The need to use a sterically compatible solvent for each of the analytes in a mixture when implementing Shpol'skii fluorimetry poses no special problems since a single solvent such as *n*-heptane or *n*-octane usually suffices to obtain the sharp-line spectra of PAH mixtures containing compounds of three to six rings.

In quantitative analyses, the inner filter and enhancing effects may introduce a bias in the analytical results provided by Shpol'skii fluorimetry in the frozen-solution mode. Such a bias can usually be eliminated by internal standardization. Since the fluorescence in Shpol'skii matrices is so highly resolved, the deuterated analog of a PAH can be used as an internal standard for determining the PAH concerned by simply spiking the original sample solution with small volumes of alkane solutions of the required deuterated PAH prior to freezing. Computerized acquisition of data for a spectral scan of 200 nm can be accomplished in barely 5 min against 1–5 h by manual means. There are, however, some additional problems that have a direct bearing on the quantitative usefulness of the Shpol'skii effect in the frozen-solution mode. Thus, the linear dynamic range usually spans less than three orders of magnitude. In addition, since most compounds are less soluble at lower temperatures, solute aggregation can occur – and hence the precision be diminished – unless freezing is accomplished fairly rapidly and the analyte concentration is relatively low.

Matrix-isolation Shpol'skii fluorimetry has been shown to eliminate quantitative artifacts from quenching and aggregation phenomena occurring in Shpol'skii low-temperature solid matrices. The linear dynamic range for the fluorescence of PAHs in vapor-deposited alkane matrices surpasses that of solid-state Shpol'skii fluorimetry. Thus, the analytical calibration graph for the fluorescence of benzo[*a*]anthracene in *n*-heptane is linear from 30 pg (the detection limit) to a maximum amount of over 35  $\mu$ g. The

usual upper limit of linearity for calibration graphs is 1–10  $\mu$ g. PAHs with subpicogram detection limits typically exhibit linear dynamic ranges of six decades. *n*-Alkenes used as matrices in the matrix-isolation mode yield quasilinear spectra similar to those provided by Shpol'skii frozen solutions. This technique has been used to resolve isomeric alkylated PAHs in various environmental matrices. The chief advantage of frozen-solution methods over matrix-isolation methods lies in their greater simplicity: preparing a sample by freezing a liquid solution is much less time consuming than performing matrix isolation.

Very complex mixtures such as coal-derived materials often result in undesirably overlapping spectra for PAHs in Shpol'skii matrices when a xenon lamp is used as the radiation source. In such cases, provided a sufficiently monochromatic source is used, the fluorescence may be selectively excited from one specific compound in a complex mixture of very similar PAHs. In practice, selective excitation usually entails using a laser for excitation. LIF in Shpol'skii matrices has been used to identify and quantify individual PAHs in highly complex coal-derived materials. By way of example, **Figure 2** shows the site-selective fluorescence of four individual PAHs in a solvent-retained coal liquid sample. The spectra were recorded following a 1000-fold dilution of the

**Figure 2** Site-specific, laser-induced fluorescence spectra of pyrene, 4-methylpyrene (4-MP), B[a]P, and B[k]F present in a solvent-retained coal liquid (SRC-11) sample measured in a frozen *n*-octane solution at 15 K. The excitation wavelengths for the PAHs are given. sample in *n*-octane. The excitation wavelengths used are shown in the figure. It should be noted that the selected excitation wavelength for benzo[*a*]pyrene and benzo[*k*]fluoranthene [B[*k*]F] resulted in weak emission from B[*k*]F and B[*a*]P, respectively, owing to partial overlap of primary absorption lines of these compounds at such a wavelength. However, the emission lines are sufficiently resolved to enable the quantitative determination of these compounds in mixtures. Note the high resolution and clean appearance of the spectra – despite the high complexity of the coal liquid sample – and the need for no fractionation steps.

In summary, there seems to be no fluorimetric alternative to excel low-temperature techniques in analytical information throughput if chemical separations are to be avoided. Massive use in the environmental field has so far been restricted by the need to use fairly sophisticated devices such as high-resolution monochromators, cryostats, and, perhaps, dye lasers. On the other hand, a number of commercially available spectrofluorimeters provide inadequate spectral resolution for use in low-temperature spectroscopic techniques. However, given the high selectivity of such techniques, their use in the characterization of complex environmental samples will continue to grow in the foreseeable future.

## Immunoanalytical Techniques

### Pesticides

The development and application of immunoassays and immunosensors based on fluorescence detection for environmental monitoring has grown significantly in recent years, with particular emphasis on monitoring of pesticide levels. Methods with fluorescent labels have the potential to achieve the low limits of detection (LOD) imposed by legislation, but high background signals have restricted in the past the LOD obtained to concentration ranges between  $10^{-9}$  and  $10^{-12}$  mol l<sup>-1</sup>. The development of solid-phase separation systems, new fluorescent probes, and new instrumentation has lowered the background such that sensitivity is now comparable with that of radioactive methods.

Background signals are mainly caused by light scattering and background fluorescence. They can be avoided by use of fluorescent probes with a large Stokes shift and maximal excitation and emission in the far-red wavelength region. Also, measuring time-resolved fluorescence can remove scattered light interferences since scattering has no fluorescence lifetime. On the other hand, reduced background fluorescence can be obtained from probes with

fluorescence lifetimes different from the fast decaying background. In addition to employing suitable labels, different detection techniques and instrumentation can contribute to the reduction of background fluorescence.

Basic test formats used in pesticide monitoring include homogeneous and heterogeneous immunoassays in batch format, flow injection immunoanalysis, and immunosensors. Phase-resolved, modulation-resolved, and kinetic measurements are used for minimizing the effect of sample matrix and improving the LODs in homogeneous assays. Fluorescence polarization is the most widely used detection technique for this test format, although fluorescence quenching and enhancement, and fluorescence lifetime have also achieved progressive applicability.

In heterogeneous immunoassays in batch format the problem of background fluorescence is reduced by separating the analyte from other fluorescent species present in the sample matrix. The use of enzymes with fluorogenic substrates in fluorescence enzyme-linked immunosorbent assays (F-ELISA) and Eu(III)-chelates in time-resolved fluoroimmunoassay (TRFIA) permits to achieve very low LODs for pesticides (e.g., between 0.023–0.3 and 0.05–0.4 µg l<sup>-1</sup> for F-ELISA and TRFIA, respectively).

In flow-injection methods and sensors the background effects are minimized, either because the matrix does not pass the detection unit or due to evanescent field techniques, where only surface bound material is excited. An additional advantage is reusability of the devices. This enables automation and online monitoring, but stability of both the reagents and the transducers has to be considered. LODs obtained by using flow-injection methods and immunosensors are comparable although detection limits can be improved by approximately one order of magnitude in flow methods that use enzyme labels because of the amplification effect of the enzyme reaction. Trends on these test formats are focusing on miniaturization. Especially evanescent field immunosensors have a great potential to become small and cost-effective devices for onsite environmental monitoring.

One can conclude that fluorimetry is not as widely used for the analysis of environmental samples as it is in other areas (particularly the life sciences). However, the high sensitivity and, under appropriate conditions, high selectivity, make fluorimetric techniques appealing candidates for the characterization of environmental materials.

## Introduction

Fluorescence spectroscopy plays an important function in modern food analysis as can be seen from its wide use in the determination of numerous food components, contaminants, additives, and adulterants. This technique has made available very sensitive and selective methods that satisfy the requirements of food analysis, which are usually very complex, taking into account the large number of species to be determined, frequently at very low concentrations, and the wide variety of foodstuffs available. Initially, the use of fluorescence spectroscopy in food analysis was limited to the determination of species with intrinsic fluorescence (e.g., vitamins, aflatoxins, and some polycyclic aromatic hydrocarbons (PAHs)), but now it is widely applied to nonfluorescent species, using several physicochemical means such as chemical or photochemical derivatization reactions. Numerous techniques involve fluorescence detection in liquid chromatography (LC), frequently using pre- or postcolumn derivatization. In addition to conventional fluorimetry, which is commonly chosen for this purpose, other fluorimetric techniques such as laser-induced

fluorescence (LIF) spectroscopy, fluoroimmunoassays (FIAs), time-resolved fluorescence spectroscopy, and derivative synchronous fluorescence spectroscopy have been shown to be useful in food analysis. There has been recent interest in the use of capillary electrophoresis (CE) with LIF as a detection system. Although the application of immunochemical techniques with fluorimetric detection in food analysis is still relatively limited, there are interesting examples of their suitability for the detection of some proteins and for the control of contamination by toxins and pesticide residues.

## Determination of Food Components

### Vitamins

Vitamins are the foodstuff components most often quantified using fluorimetric means. There are several official fluorimetric methods for the determination of three water-soluble vitamins: vitamin B<sub>1</sub> (thiamine) (AOAC 942.23 and 957.17), B<sub>2</sub> (riboflavine) (AOAC 970.65 and 981.15), and C (ascorbic acid) (AOAC 984.26). Thiamine is determined by oxidation to fluorescent thiochrome with alkaline hexacyanoferrate(III) or an alternative oxidant (Figure 1). The method is quite simple, reproducible, and selective and provides good recoveries. Many LC methods for thiamine determination in foods have

## Determination of Food Components

### Vitamins

Vitamins are the foodstuff components most often quantified using fluorimetric means. There are several official fluorimetric methods for the determination of three water-soluble vitamins: vitamin B<sub>1</sub> (thiamine) (AOAC 942.23 and 957.17), B<sub>2</sub> (riboflavine) (AOAC 970.65 and 981.15), and C (ascorbic acid) (AOAC 984.26). Thiamine is determined by oxidation to fluorescent thiochrome with alkaline hexacyanoferrate(III) or an alternative oxidant (Figure 1). The method is quite simple, reproducible, and selective and provides good recoveries. Many LC methods for thiamine determination in foods have

**Figure 1** Formation of fluorescent derivatives of vitamins B<sub>1</sub> and C.

been developed using pre- or postcolumn conversion to thiochrome, which entail a wide variety of chromatographic modes and elution techniques.

Riboflavin is commonly determined fluorimetrically, for instance in milk, by its strong native fluorescence at pH 7, which arises from the extended conjugation and rigidity of the nonribose portion of the molecule. Another fluorimetric method involves conversion of riboflavin into its fluorescent derivative lumiflavin using ultraviolet (UV) irradiation. Mixtures of thiamin and riboflavin in foods such as cereal products have been resolved using LC with fluorimetric detection.

Vitamin C is another soluble vitamin frequently determined in foodstuffs using fluorimetric detection. It is most often oxidized to dehydroascorbic acid with  $\text{HgCl}_2$  or 2,6-dichloroindophenol, which is subsequently reacted with *p*-phenylenediamine to form a fluorescent quinoxaline derivative (Figure 1). The method can be implemented in an automated fashion. The determination of total vitamin C (ascorbic and dehydroascorbic acid) in foods (vegetables and fruits) is also of great interest. The recommended method uses reversed-phase ion-pair LC and fluorimetric detection. Total vitamin C and total isovitamin C (erythorbic and dehydroerythorbic acids) can be determined similarly by prior extraction with trichloroacetic acid and precolumn derivatization, wherein ascorbic and erythorbic acids are oxidized enzymatically and total dehydroascorbic and dehydroerythorbic acids are treated with *o*-phenylenediamine.

The fluorimetric determination of vitamin B<sub>6</sub> compounds (pyridoxine, pyridoxamine, pyridoxal, pyridoxamine 5'-phosphate, pyridoxal 5'-phosphate, and 4-pyridoxic acid) in foods by measurement of their native fluorescence entails a prior LC isolation. Some of these determinations involve postcolumn derivatization with sodium bisulfite in a phosphate
